tions have been drawn up to prevent the adulteration of food and the poisoning of water, scarcely any attention has been devoted to the prevention of the admission of noxious gases and poisonous vapours into the air of our habitations. Carbonic oxide is a poison of the deadliest character, and gas jets are freely used which deliver copious discharges of this dangerous gas into the atmosphere of our rooms. If we were consistent in our legislation, we ought to forbid the use of any burner which thus poisons the air. A man at rest exhales 0.0424 cubic feet of carbonic acid gas (CO<sub>2</sub>) and 1189 cubic feet of air per pound weight per hour, while a gas jet burning 5 cubic feet of coal gas, exhales 4 cubic feet of CO<sub>2</sub>. The maximum proportion of CO<sub>2</sub> to air consistent with health is 6 volumes in 10,000, 10 volumes affect the heart, and 30 volumes produce headaches. Rheumatism, bronchitis, and other ailments proceed from higher proportions. In fact, 5 cubic feet of gas requires 8,000 cubic feet of pure air per hour to maintain it healthy. The electric light requires no such provision.

That the electric light is a powerful element of health is evidenced by the fact that those who use it not only feel all the better for its introduction, but their appetite increases, and their sleep improves, and the visits of the doctor are reduced in frequency. Workpeople work all the better, and absences from illness are far less frequent. In the Savings Bank in Queen Victoria Street, London, where 1,200 persons were employed, the absences from illness were so far reduced, that the extra labour gained paid for the electric light. In Liverpool and many other places the same result has been observed.

The influence of artificial light on the eyes has a very important sanitary bearing. Why is it that there is so much short-sightedness in the present day? Is it due to our mode of producing light? Some assert that the injury to the eyes is due to the heat rays and not the light rays. If that be so the electric light must be much less injurious than any other. On the other hand, no one can have experimented with arc lamps without having had his retina painfully affected, which leads one to think that the ultra-violet rays have some influence. No one has, however, ever complained of the influence of a steady glow lamp upon the eyes, and it is possible to read and to write for many hours by such a light without experiencing the least fatigue.

The electric current is not altogether free from being a cause of fire, and though its use is by no means very general, still it is used sufficiently to make itself felt as an element of danger in this respect. The following table shows the number of fires in London which can be traced to the different methods of lighting:—

	1887.	1888.	1889.	Total.
Lamps ... ..	245	205	257	707
Gas ... ..	188	197	209	594
Candles ... ..	142	113	136	391
Electricity ... ..	0	1	2	3

The progress of the electric light in our homes has been much more rapid in England than in any other country, but its employment for street-lighting, for shops and manufactories, has been infinitely more rapid and extensive in the United States than with us. In America the growth has been enormous. There are now 250,000 arc lamps, illuminating the public streets and shops, and 300,000,000 glow lamps in dwellings, stores, and workshops.

The following table shows the development of the Berlin Central Stations:—

Station.	Effective of Horse-Power.						When Completed.
	1864.	1887.	1886.	1887.	1888.	1889.

The progress in England has been very much checked by inordinate speculation, and by terrible failures in some of the earlier work done. There is something very captivating in the practical applications of electricity, and something romantic in its mystery. The neophyte has rushed into it with remarkable fervour, and the lessons of failure have in consequence been very severe. The users of the light have also been paying heavily for the education and experience of amateur tradesmen and inexperienced contractors, and have neglected to avail themselves of the professional services of the experienced electrical engineer. People who would not build houses without the architect, nor construct bridges without the engineer, nor make their wills without the lawyer, rush wildly into the use of electricity without any professional assistance, where, above all things, experience and knowledge are essential to prevent disaster and disappointment. Large installations have been completed without specifica-

\* Abstract of paper read before the Sanitary Institute, Brighton, August 26th.

tions to guide the contractor, and without inspection to see that the work has been properly done. The user has paid violently for his temerity, and fires and accidents have been the result. The heavy price of wiring a rented house, and the expensive character of the fittings proposed, have deterred many from adopting the light, even when it is within their reach. Highly insulated wire is unfortunately expensive. All cheap wires are nasty and dangerous. There is nothing that becomes the electric light better than simplicity, and its effect is frequently marred by elaborate brass work. It possesses also most active and widespread opponents, both in oil and gas—opponents who have benefited by its introduction, and who are not slow to profit by its advance. The improvements in gas and oil lamps are as marked as the advancements in electric light, and as means of artificial illumination alone—that is as far as light-giving power is concerned—there is little choice between the three, but oil and gas cannot lose those elements of discomfort and ill-health which differentiate them from the cool and pure glow lamp.

A very important question arises for discussion. Legislation has slipped in to place the virtual control of the supply of electrical energy in the hands of the local authority of the district to be served. Is this supply to be the result of the capital of private enterprise, or is it to be effected by raising money on the security of the rates?

It is argued that the supply of electricity being a purely commercial undertaking, it should therefore be carried out by a limited liability company. The Acts of 1882 and 1888 do not encourage monopoly, but rather court competition, and competition attracts capital. Competition properly regulated and controlled secures economy in supply, and certainly enforces economy in working, while it encourages improvements, and induces perfection of apparatus and novelty in processes. These arguments are plausible, but are easily refuted by those who desire to uphold vested monopolies. Direct competition always means ultimately enhanced cost to the public, for the same public has to pay for double plant, and each competitor only gets half revenue.

The supply of light is in precisely the same category as the supply of water or the supply of gas, and the days have certainly passed when the public will tamely submit to the transference of their right to such vested interests as those of gas or water companies.

It is very easy to argue *pro* or *con* on each side. The local authority has to regard the security of traffic, the safety of person, the repression of crime, and the proper supervision of the premises of its ratepayers. It is the custodian of the public interests. It has to control the health, cleanliness, comfort, and beneficial sanitation of its habitable dwellings. It therefore must secure the best light, and if it can do this, and at the same time relieve the rates which are generally creeping up to dangerous dimensions, then its action would be wise and economical. But it would be entering into commercial rivalry with an active competitor—the gas companies; and its commercial control by such a shifting authority as a committee of a Town Council or of a Local Board, subject to the changes of political warfare—to the vagaries of press dictation, and to the fear of November elections—is a very doubtful proceeding. On the other hand, in many instances, such bodies have successfully dealt with the water question, the tramways, and even with the gas. In fact, one-third of the gas capital (21 millions) in this country is in the hands of 173 Local Authorities, and more than half a million of profits go to the reduction of rates.

Bradford has already grappled with the question. It has established a central station for the supply of the electric light. Brighton, St. Pancras, and Bristol are doing the same, and many other places are following suit. They are shying at the probability of handing over their districts to a speculative company, with a virtual though not a legal monopoly, to supply electrical energy for 42 years. Many corporations contemplate a middle course. They have obtained the power for themselves, but they have farmed for shorter terms the right of supply to private enterprise, which can do what they are afraid to do, viz., speculate and experiment. The Board of Trade has sanctioned and facilitated such a transfer of statutory rights.

It is surprising that gas administrations in England have not been more enterprising in developing electric lighting. In Vienna, Rome, and Stockholm the gas companies have established central stations, and the progress of the industry in these cities is very great. The proper function of gas is to supply heat, not light, and as a source of power it has a future more brilliant than its past. If it could be supplied as fuel it would remove the troubles of coal transit and storage, of ash and dust removal, of smoke and of stoking. It has even been shown that it is cheaper to convert coal into gas on the spot, and to use the gas as the source of power, than to apply the coal direct for the production of steam in boilers. The waste of energy in the use of coal is enormous. The energy contained in one pound of coal if burnt in one hour is theoretically sufficient to supply 5·6 horse-power for that hour. The best practical result yet obtained by the steam engine is scarcely one horse-power.

The electric light is unquestionably the light of the future. Its use is advancing with leaps and bounds. Not only is it naturally the proper source of light, but economically it must eventually supplant its rivals. When electrical energy is generally distributed through our towns, and its supply is continuous, and properly controlled, so that it is always within the reach of all; and when means can be devised to wire up houses as cheaply as they are now fitted for gas, everyone will take it, not alone for its beauty, but because it is, above all, a source of health and comfort.

## THE BERMUDA-HALIFAX CABLE.

THE following particulars of this cable may be of interest to our readers:—

The core is composed of seven copper wires stranded, weighing 120 lbs. per N.M., and of three coats of gutta percha, weighing 150 lbs. per N.M. The core is covered throughout with a serving of jute yarn, steeped in a preservative mixture and then whipped with 3-ply jute yarn.

The conductor resistance is stated to be 10·5 ohms per N.M., at a temperature of 75° Fahrenheit; the dielectric resistance after 24 hours' immersion in water at the temperature of 75° Fahrenheit, was to have been not less than 1,000 megohms after one minute's electrification.

In the deep sea type the core is sheathed with 16 galvanised iron wires, each ·099 of an inch in diameter; the outer covering consists of two coats of Russian hemp laid on in opposite directions, and three coats of bituminous compound. The weight of this type, wet in air, is about 1·8 tons per N.M. The sheathing of the light intermediate cable is composed of 12 galvanised iron wires, each ·165 of an inch diameter; the outer covering is the same as in the deep sea type. The weight of this type, wet in air, is about 3·5 tons per N.M. The core, in the heavy intermediate type, is sheathed with 12 galvanised iron wires, each ·220 of an inch diameter; outer covering same as before. This type weighs, wet in air, about 6 tons per N.M.

For the Bermuda shore end the core is first sheathed with 12 galvanised iron wires, each ·165 of an inch diameter, a sufficient serving of jute and compound is then laid on, and this is then covered with an outer sheathing of 12 strands of three wires each, each wire ·203 of an inch diameter. The external covering is the same as before. This type weighs about 19 tons, wet in air, per N.M.

According to the *Bermuda Royal Gazette*, the Halifax shore end is of a lighter description, having only one sheathing, and weighing only about 10 tons per N.M.

The *Westmeath*, a steamer chartered by Henley's Telegraph Company for the laying of the cable, is a vessel of some 4,500 tons. She left the Thames on May 23rd, carrying 874 N.M. of cable. She was under the command of Captain Stonehouse, the engineer-in-charge being Captain Stiffe, late of the Indian Marine. Mr. Peake, of the firm Clark, Forde and Taylor, represented the Halifax and Bermudas Cable Company.

The *Westmeath* anchored at Bermuda on the 6th June, and left on the 12th to sound along the route of cable, completing the soundings commenced by the *Challenger*. The vessel arrived at Halifax on June 16th. It is stated that the soundings were taken 100 miles apart, except near the land, where they were made at close intervals. The deepest water found is said to have been 2,820 fathoms, with a bottom temperature of 34·4° Fahrenheit. The laying was commenced from the Halifax end on the 25th June, arriving off Bermuda on the 30th, the final splice being made on the 7th July, some difficulty having been experienced in the laying of the shallow water portion, light draught vessels being employed for the purpose. The total length laid was, we understand, about 850 N.M.

The capital of the company is £120,000, in 4½ per cent. first mortgage debentures, and £50,000 in ordinary shares of £5 each. The English Government grants a subsidy of £8,100 per annum for 20 years.

It is stated that considerable traffic will be obtained between Bermuda and New York, and that some revenue will arise from ships which, it is hoped, may make the Bermudas a port of call. We presume that some business beyond that which may proceed from casual winter visitors from the States, or from an occasional vessel in distress, is anticipated. No doubt the cable is of importance as connecting two British naval stations, but this fact does not necessarily imply a paying investment.

## REVIEWS.

*Electric Light Fitting: A Handbook for Working Electrical Engineers.* By JOHN W. URQUHART. London: Crosby Lockwood and Son, 1890.

The volume before us is an attempt to state in the simplest language the precautions which should be adopted in installing the electric light, and to give information for the guidance of those who have to run the plant when installed. It is addressed to intelligent men who are engaged in the electrical industry, or being trained for it, special attention being given to the branches known as "fitting" or "wiring." As might be expected, the contents cover a somewhat extended area of practice, and a deal of information which may prove useful to the expert as well as to the working electrician is given. As a book justifying its pretensions it can be recommended, though in many instances we do not find ourselves in agreement with the author. At page 11, for example, the author is not at all clear regarding the reason for giving the brushes a lead, and does not seem to know that when a lead is given they are still almost at right angles to the lines of force, the latter being twisted, however, by the armature current. We should like to know the names of the electricians referred to who have made the calculations showing that machines without iron in their armatures require no lead. On page 32 the author refers to the pumping or pulsating of arc lights, and mentions that extinctions and rapid self re-lighting sometimes occur. This is unfortunately true, but Mr. Urquhart does not explain that the reason of this misbehaviour is mostly due to faulty proportion in the dynamo, which has to be carefully guarded against by those who manufacture closed coil arc machines. The author is a little behind the times in advocating the insulation of the armature core from the shaft. No good machines are made so now-a-days, nor is it necessary, even for the highest E.M.F. The remarks about the coupling of alternators in parallel are extremely weak, and the instructions to the attendant are not at all clear. Regarding the running of arc lamps in parallel, it is said, they "work very well when fitted with resistances or choking coils, as they are called." Here the author fails to distinguish between resistances and choking coils, two things which are essentially different in principle and construction. We should say the author's knowledge of arc lamps and their working has been derived mostly from books.

Coming to the question of loss between the dynamo and the lamps, a limit to this is set at 5 volts. In our opinion, this variation is far too much to allow, and  $2\frac{1}{2}$  volts would be nearer the mark. In talking of the series system of incandescence lighting, the author says that it is impracticable when carried beyond a few lamps, as a line of 50 lamps of 100 volts would call for 5,000 volts. Of course no engineer in his senses would for a series system use 100-volt lamps, so this argument is quite untenable. An alternator working direct on to lamps is said to be less liable to breaks-down than a direct current machine, as there is no commutator to get out of order, but surely the exciter commutator is as likely to go wrong as would be the commutator of the large machine if it were direct instead of alternating, so here we fail to see an advantage.

There are many more statements to which we take exception, but space will not permit us to notice them. Though there is much that might be objected to on the grounds of scientific inaccuracy, the book, on the whole, is well worth the perusal of the workman, for whom it is written. If we cannot have a practical work scientifically accurate, we must be content with the nearest approach to it we can get.

*The Labour Movement in America.* By RICHARD T. ELY, Ph.D. of Johns Hopkins University. London: William Heinemann.

Trades Unionism and Socialism have of late become such important factors in the economy of the world

that it is no longer prudent for any thinking man to ignore their existence and drift. Literature on these subjects is by no means scarce; almost every leader of working men has written articles, pamphlets and books thereon, and we find a chapter here and there in treatises on political economy, but most of these are somewhat biased, and therefore do not reveal the true state of affairs. Prof. Ely appears to have studied the labour questions from all points of view, and he is by no means a novice, having already written two books of a kindred nature, viz.: "French and German Socialism" and "The Past and the Present of Political Economy," besides numerous articles in American magazines.

In his preface the author addresses working men, expressing sympathy with many of their movements, not, however, without judicious qualifications: "Much that is done in the name of labour I regard with abhorrence. In the same way should the reader understand my admiration for the Knights of Labour. I believe it is a grand society, but I dissent from some of its principles, and from its course in some localities. Individual knights and individual assemblies have been guilty of outrageous conduct with reference to their employers, the general public, and their fellow workmen. Their deeds have sadly injured the cause of labour." Prof. Ely warns working men against violence: "Destruction of the property or lives of others cannot help you or enrich you. Your triumph can come only by peace. There is much that is bad in existing social arrangements, but there is also much that is good, and this good has been procured by struggles of centuries. With a full appreciation of all that is sad and disheartening in the condition of the masses, I believe that, on the whole, the lot of mankind was never a happier one than to-day." Again: "If your demands are right, if they are reasonable, then you will win, and hold your gain. The world will listen even to socialism, if properly presented. Educate, organise, wait."

The author then discusses with a masterly mind "Early American Communism, The Growth and present Condition of Labour Organisations in America, The Economic Value of Labour Organisations, The Educational Value and other Aspects of Labour Organisation; Co-operation, Modern Socialism, The Socialistic Labour Party, The Strength of Revolutionary Socialism—its Significance," and finally, "Remedies." There is also a copious appendix, setting forth the principles advocated by various associations and labour conventions.

We feel tempted to quote passages from every chapter. The book is full of interest, and it must prove equally instructive to employers, to *employés*, and to students of political economy. We are ever confronted with strikes, and wars between capital and labour. Prof. Ely suggests several remedies worthy of consideration.

#### VARYING THE FORCE OF AN ELECTRIC DISCHARGE BY DIFFERENTLY COMPRESSED CARBON POWDER DISCOVERED BY MUNCK, OF ROSENSCHOLD, IN 1835.

By A. M. TANNER.

It has generally been held that du Moncel first discovered the peculiar property which carbon and certain other semi-conductors have of varying their resistance when subjected to a change of pressure. Upon the advent of the Hughes microphone and Edison carbon telephone, the question of priority of discovery of the variable resistance of carbon with pressure was exhaustively discussed in the journals of that period, and the credit of prior discovery was awarded to du Moncel.

During the year 1887 I drew attention, in the *Electrical World*, to the fact that Beetz, in his experiments

made in the year 1861 to test the electrical conductivity of carbon, placed carbon powder or spongy platinum in a glass tube, and subjected it to variable pressure by piston-shaped electrodes in order to obtain a change of resistance. This same method was subsequently embodied in the well-known Clerac carbon rheostat, upon which Edison founded his first carbon telephone. In fact, it would appear that Edison had no knowledge of the earlier experiments of du Moncel, Beetz, and Clerac, when, according to Prescott's work, "The Speaking Telephone, A.D. 1879," he is quoted as saying that he applied to the telephone "the peculiar property which semi-conductors have of varying their resistance with pressure," a fact discovered by him while constructing rheostats in which were employed powdered carbon and plumbago in glass tubes.

I will now proceed to show that the prior discovery of the property that the electrical conductivity of carbon is varied by pressure, is due not to du Moncel, Beetz, Clerac, Edison, or others, but to the Swedish physicist Munck, of Rosenschöld, who published certain experiments on the capacity of solid bodies for conducting electricity in Poggendorff's "Annalen der Physik und Chemie" for 1835, Vol. XXXIV., p. 437. After describing the apparatus used in his experiments, such as a large Leyden jar, and electrometers of different capacity, and the action of electrostatic discharges upon various bodies, the author continued, on page 459, as follows, viz.: (Note.—I have endeavoured to translate the German as literally as possible)—

In order to ascertain how carbon powder, variably packed, will be affected by the action of the electrical discharges I placed the calcined carbon mass (obtained by calcining wood carbon in a closed crucible) very loose in the longest glass tube.

The discharge of 25° of the first electrometer was felt at a distance of 13 inches. A discharge of 25° of the second electrometer had no influence upon the conductivity; heavier discharges, however, of 35° to 40° of the quadrant electrometer increased the conductivity, so that the shock of a discharge of 11° was felt at the same distance. After this the carbon powder was taken out, but immediately placed again in the same tube, and moderately packed together. The degree of conductivity was now 20½°, and after strong discharges had been passed through the same, the shock was already felt at 17°. Thereupon the carbon powder was placed in the glass tube for the third time, and very strongly packed. The degree of conductivity was now raised to 33°. By the action of stronger discharges the conductivity was further increased, and the shock of the first electrometer was made perceptible at 16°.

On page 461 the author says that he is of opinion that the phenomenon of the increase of conductivity is due to the change of position, or displacement of the smallest particles or granules of carbon or other material operated upon.

It will readily be seen that Munck, of Rosenschöld, discovered the variation of electrical resistance that carbon powder will undergo when subjected to a change of pressure. It is true he did not use voltaic or current electricity, but discharged a Leyden jar through differently compressed granular or powdered carbon, and he found that the conductivity increased when the granules of carbon were brought in closer contact with each other. This is exactly the principle involved in that class of telephone, and other rheostats where compressible granular or powdered carbon is used.

### THE "STELLA" LAMP.

THE following is a translation of a note presented by M. le Comte de Gerson to the Académie des Sciences, and to which we referred last week in our "Notes":—

"The lamp, which is the result of investigations made by an English company, which numbers amongst its members some of the most eminent English savants,

has been tested at the Ecole des Mines, and, since, by the mining company at Anzin, in one of its mines the most infected with fire damp.

"The lamp weighs about 1,600 gr., and its illuminating capacity is about that of a candle. It is guaranteed to burn with perfect regularity for a period of 12 hours, but actually it possesses an effective capacity of 14 and even 16 hours' duration. It takes five hours to charge with a current of 1 ampère and 4 volts. It is composed of an accumulator, consisting of two ebonite cells, each of which contains five plates 75 mm. long, by 45 mm. wide, and so arranged as to be protected from exterior shocks. Two of the plates are composed of solid lead peroxide, known as *lithanode*; together they weigh 180 gr., and possess a capacity for useful work of 7 ampère hours. The three others are composed of spongy lead, maintained by a support which is extremely light, and offers a very feeble resistance and a high conductivity; practically it is never used. The more the lithanode is charged the better it becomes, and disunion of the plates never occurs. As there is no contact between the plates, no local action takes place in the accumulator when this is at rest. The total capacity of the accumulator is 28 watt-hours. Thus,

$$7 \text{ ampère-hours} \times 4 \text{ volts} = 28 \text{ watt-hours.}$$

"In ordinary mining, the incandescent lamp requires about 5 ampère-hours in 12 hours' lighting.

"The electrolyte used with the accumulator is sulphuric acid diluted, the specific density of which is 1.170.

"The exterior case is of galvanised steel, which is not liable to be rusted by damp. There is a space of about 60 mm. between this and the accumulator; it is padded with rubber, to avoid damage from sparks to the accumulator's ebonite case.

"A little below the centre of the anterior face of the lamp there is a small glass lens, behind which a small incandescent lamp is placed, which, being mounted upon a spring, is drawn into the lamp when the latter receives a shock through the breaking of the first glass. Above the lens there is a commutator, which enables the lamp to be lighted or extinguished at will, so that, in case of a falling in of the works in the rear of the workmen, they would be still in possession of a light for as many times 10 hours as they had lamps.

"The safety is absolute against any imprudence on the part of the miners. Lamps have been broken in gases much more explosive than fire-damp without an explosion. Moreover, the lamp is to be recommended for its simplicity, cheapness, and the duration of its lighting."

### THE INDUSTRIAL UTILISATION OF THE COUNTER-ELECTROMOTIVE FORCE OF SELF-INDUCTION.\*

By THOMAS D. LOCKWOOD.

It may as well be confessed at the outset that although my production has cost me considerable thought, it does not claim to advance any original ideas. Its claims to attention are based solely upon its merits as a chronicle. There seems to be among the modern race of electricians not a few who regard that species of counter-electromotive force which is the subject of this paper, as being the only species in the genus. While, of course, this view is erroneous, it is easily accounted for by the notorious fact that the American electrician, as a class, has little time to study. The fact, however, while it is indeed as I have termed it, "notorious," is still to be deplored; for it is certain that were electricians fully informed not only of the researches which took place before their own, together with the results of the said researches, whether these results took the form of success or failure, there would be much less valuable time wasted in supposed original research; there would be far fewer valueless inventions produced; and there would be a much smaller amount of subsequent vexations and useless litigation.

While counter-electromotive force, generally speaking, is a

\* A paper read before the general meeting of the American Institute of Electrical Engineers, Boston, Mass., May 21st, 1890.

genus; the counter-electromotive force of self-induction is a species, and while an illustration of this statement will no doubt to most of us be an operation something in the nature of carrying coals to Newcastle, or water to the Mississippi valley, I cannot believe that it will be a waste of time, since doubtless we have many members who have not fully considered the subject.

Consider for a moment a definition of electromotive force. What shall we say it is? It certainly is not a natural force like gravitation, and I do not think we can do better than concede that we call it a force, simply because it is convenient so to do; and define it as any agency tending to set up that form of motion or vibration which we call electricity; or, if you please, any agency tending to the manifestation of electricity.

We are constantly hearing that a current of electricity is the result of a difference of potential between two points connected by a conductor, but though this statement, through constant repetition, has come to be, as it were, "human nature's daily food," I am inclined to consider it as being after all but a mathematical way of saying that a current of electricity is the necessary result of an electromotive force provided with a closed conducting circuit. For it is the electromotive force which first determines the difference of potential, which therefore may be considered as being a kind of initial result. Following out this train of thought, it appears then that electromotive force is a function of the source or instrumentality which develops the current, and expresses the totality of difference of potential in the entire circuit; and while we may properly speak of the difference of potential, or fall of potential between any two points on the circuit, I think we can not with equal propriety speak of the E.M.F., in any other way than as something pertaining to the source.

And further consideration of the same idea shows the incorrectness of the popular phrase often used of late years even by many eminent and able electricians, "a current of so many volts," the electromotive force being in no sense, near or remote, an attribute of the current.

To run counter to anything is to run against it, to run in opposition to—to act oppositely; and so a "counter electromotive force" may be defined as any agency tending to develop a current of electricity in a circuit, opposite in direction to that of the current excited therein by the initial electromotive force.

A familiar instance is that of connecting up in an electric circuit a certain number of cells in opposition to a number of other cells. This constitutes a primary counter-electromotive force, and its inclusion in the circuit reduces the current in two ways; first, by reducing the acting electromotive force to a value equal only to the algebraic sum of two opposing forces; and, secondly, by adding internal resistance of the value of the cells added in opposition.

Another familiar illustration is found in that ingenious class of dynamo regulator which acts by causing the opposing brushes to creep around the commutator, and, according to the work which is being done in the external circuit, to include in the circuit (by increasing or decreasing the lead of the brushes), a greater or less number of armature coil sections exerting an electromotive force in opposition to the electromotive force which is developing the working current.

In these cases a utilisation is made of counter-electromotive forces deliberately organized for the purpose, but they are not counter-electromotive forces due to self-induction.

At a very early period in the history of voltaic electricity it was discovered that there was some deteriorating force at work in every voltaic battery which depreciated the current to a much greater extent than exhaustion of the liquids or consumption of the solid elements could account for; and, in 1801, Gautherot found\* in this phenomenon, which has foolishly been called "polarisation," the germ of the secondary cell. He discovered that wires of platinum or of silver which had been used to decompose salt water acquired a power of themselves, yielding a current when placed in acidulated water, and could cause muscular contractions of a frog's leg, and produce the galvanic test. And subsequently it was ascertained that the operation of a voltaic battery tended to coat the negative plate with hydrogen, which tended to set up a counter-electromotive force between the hydrogen and the surface of said plate, which thus reduced the available energy of the battery, and that this action could be transferred to the electrodes of the same battery, if placed in a separate decomposing cell, and there tended to form electrically opposed surfaces, which could themselves be used to develop a current in a direction opposite to that of the original current. As we all know, this operation, long regarded only as an unmitigated evil, is now utilised in the formation and operation of cells adapted for the electrical storage of energy.

The counter-electromotive force of self-induction distinct from the foregoing, is that discovered by Prof. Henry; and its most important use is that which has been mainly brought out in association with the employment of alternating or other currents for the purpose of regulation. By reason of the fact that this utilisation has proved to be overwhelmingly important, the electrical fraternity has partially lost sight of many earlier and contemporary instances of the useful employment of self-inductive electromotive force; which is indeed a close analogue in its character, mode of generation, and capabilities of use in regulation to that developed and utilised in the operation of electro-motors.

Firstly—I desire to point out that though Henry was the first to study and discuss self-induction, he was not the first to notice its effects.

Until quite recently I, together with nearly everyone else, had supposed that the earliest published notice of this phenomenon was Henry's account\* of his observation, published in 1832; but I have, in my researches on the subject, dug out the fact that this is not so. I find that an experimentalist, Vassali-Eandi by name, records that,† with a pole of 50 pairs, he found that the fluid passed along a copper wire plated with silver, 1,151 feet in length, in a time incommensurable; the shock in this case was three times as strong as that experienced by immediately touching the two extremities of the pile.

The above isolated statement of facts stands, I believe, alone, and there is no record that it led to further research.

Henry, on the contrary, perseveringly pursued, and made himself master of the subject, and the record of his original observation, brief though it is, details the appearance of a vivid spark on the breaking of a battery circuit, if a wire 30 or 40 feet in length be included in that circuit, shows that the effect is increased by coiling the insulated wire into a helix; and that the effect depends in some measure on the length and thickness of the wire. The note concludes with these remarkable words: "I can account for these phenomena only by supposing the long wire to become charged with electricity, which, by its reaction on itself, projects a spark when the connection is broken."

This, though brief, is then the first analytical notice of the electromotive force of self-induction, so long erroneously denominated after its result, the "extra current."

It is unfortunate that Prof. Henry did not for some time pursue the subject, and we do not hear from him again until March, 1835.

Meanwhile his great contemporary, Faraday, had taken it up, pursuant to an observation of one William Jenkin, and showed self-induction to be a corollary of his former masterly experimental researches in magneto-electro induction.

Faraday notes‡ the following points: "Self-induction exists in simple helices as well as in electro-magnets, though not to the same degree.

Helices are superior in developing induction to straight wires, and long wires to short ones.

Self-induction practically disappears when the conductor is permitted to inductively act upon a neighbouring closed circuit.

That the amount of self-induction depends on the length of wire exposed to inductive action.

An iron core within helices much exalts the action of self-induction.

The self-inductive effect depends not "upon a permanent state of the core, but on a change of state."

Henry now again takes the matter, and in a consecutive series of papers, practically runs it to earth.

§ In a paper of March, 1835, he gives more in detail, some of the conditions of the development of self-induction. A long wire is better than a short one; a helix better than a straight wire of equal length. He also describes a shocking coil, and also a deflagration coil of but one wire, in which self-induction is involved.

|| A little later he elucidates the origin and properties of self-induction, and records that some additional energy appeared when iron was used as a core, but not much, because his coils were flat, and not elongated helices. He ascribes all of these effects to dynamical induction, and shows that in a coil of a number of convolutions, the convolutions act inductively on each other, and inferentially that the energy of the self-induction is the sum of that of the different coils.

¶ In a third paper further experiments in self-induction or with the extra current, as it was then called, are discussed. We learn that the electromotive force of any self-induction coil within certain limits is dependent upon the length of the coil.

That the form of the coil has considerable influence on the intensity of the action. In the experiments of Dr. Faraday, a long cylindrical coil of thick copper wire inclosing a rod of soft iron was used.

This form produces the greatest effect when magnetic reaction is employed.

The "extra current" of self-induction developed in a coil is controllable by the presence of an immediately adjacent inde-

pendent coil. It is energetic when the circuit of the adjacent coil is open, but absent when the adjacent circuit is closed.

Of course it is impossible in this paper even to indicate the many good things which are spread before the reader of the researches of both Faraday and Henry. They are well worth study, and in fact they laid a solid foundation for the work which is being done now.

Both discovery and invention are displayed in their work, much of which has only found its sphere of action within the last four years; for it is emphatically true, as has been said by Mr. W. H. Preece, "that though we are accustomed to hear that necessity is the mother of invention, the child is, as a matter of fact, often born before its parent."

As is frequently the case with electrical discovery, self-induction was for long recognised, that is for the most part, and by the generality of electricians only as an unwelcome guest whose parting was to be speeded.

It was manifested mainly by an undesirable spark appearing upon the break of electric circuits in telegraphic, scientific and medical apparatus, and tending to burn away, or oxidise, contact points; while in the case of the two wire induction coils its effect was to reduce the spark passing between the terminals of the secondary; and many have been the expedients, wise and otherwise, which were devised for its banishment. Many of these were patented, more were not, inasmuch as the fever for patenting everything from a solar system to a thought had not then come into fashion.

Examples of this class of expedient are respectively:—

British Patent, No. 12,772, September 20th, 1849, granted to those old heroes of electric lighting history, Staite and Petrie, which has for its 18th clause a mode of "preventing the spark when breaking contact in galvanic circuits. A thin platinum wire may still convey some portion of the current after the main circuit is broken, or a series of sufficiently long conductors may break contact one after the other." The preferred way, in plain English, was to connect a fine wire as a shunt round the break, and thus to furnish a closed circuit in which the self-induction circulated its current of breaking.

United States Patent, No. 33,269, granted to J. E. Smith, September 10th, 1861, for a means of preventing the spark between the local points of a relay on breaking the circuit—shunting the break by a wire having two terminals dipping into a bottle of water.

Moreover, as is well-known in the ordinary induction coil, the action is emphasised by shunting the primary break by a condenser, as first suggested by Fizeau.\*

This, as I shall point out later, is a real instance of the industrial utilisation of self-induction.

Other early investigators in this line reduced the spark of breaking the circuit, by wire shunts also.

Although, as I have stated, the recognitions of self-induction were mostly recognitions of an adversary, there were one or two early instances where the enemy was subjugated, and made to expend his energy usefully. The most notable instances of this are the single wire spark coils of Page and Callan,† which were made especially with a view to exalt the self-inductive effects, and with which metals were fused, and electrolytes were decomposed.

These were the forerunners of the spark coils used at the present day in electric gas lighting, and comprising a single long coil wound to a suitable length upon a long core of iron wires.

There can, however, be no doubt that the principal attempts to make useful the counter-electromotive force of self-induction, and likewise the principal successes achieved, have been in the line of controlling, regulating, or modifying the original, initiatory, or primary currents from which it has been developed.

I have compared this to the transposition of a given number of battery cells.

This analogy is however imperfect, since in cells of battery we may for the sake of argument regard the E.M.F. as being practically constant. Certainly they will in no sense regulate themselves in accordance with conditions automatically, but the inductive resistance *will* do this. For it is dependent for its efficiency as a generator upon the strength of current flowing through it. Therefore, if the current through it due to the impressed electromotive force from any reason falls, the counter-electromotive force will also diminish, and thus will permit a greater amount of the initial force to act; or, in other words, will permit the impressed energy to become more effective. Suppose we have in the main circuit of an alternating dynamo, supplying a number of incandescent lamps in bridges uniting its mains, an adjustable resistance; and suppose the inductive resistance, which we may also regard as a counter E.M.F. generator, to be initially adjusted, so that all of the lamps burn brightly; then within limits of considerable range the current will be kept steady, even though the applied E.M.F. fall or rise, or though the external resistance of the circuit be varied by lighting or extinguishing lamps.

For if lamps be extinguished and their branch circuits be opened, the external resistance rises and the current falls. It is true that the reduced current has not now so many branches to divide through, and that therefore self-regulation even without counter E.M.F. might be expected, but in systems of considerable magnitude it is not found to act practically, as well as it theoretically should. But here the useful effect of our self-induction regulation comes into play; and since the current acting upon the

regulator is lowered, it is caused to develop a counter E.M.F. of less value, and thus to oppose less energetically the applied E.M.F., which therefore is brought to a greater extent into action, to overcome the increased resistance, and to maintain the normal current for the remaining work. So, if the applied potential falls, the current in consequence falls with it, and the counter E.M.F. developed falls also, and enables more of the applied E.M.F. to come into action. And the converse is true, if the current in the circuit from any other cause rises. Such an appliance would be still more convenient in connection with an arrangement of arc lamps fed by alternating currents, and connected up in parallel circuit, since the resistance of arc lamps would constantly be changing.

This has been so prominently brought before us by its most modern employment, namely, by its well-nigh involuntary use in the distribution of electricity by means of alternating currents and transformers or converters, having their primaries connected in parallel between the two mains of the source; and by the inductive resistance regulating device, patented by John Hopkinson, in England, August 3rd, 1881, No. 3,362; and in the United States, November 5th, 1889, No. 414,541, that many persons have actually been led to believe that such use is really a new thing.

The employment in the regulation of electrical distribution of counter-electromotive forces set up by the working currents themselves, and proportioning themselves automatically to the work being done, is one of the most valuable and interesting features of modern electrical work; and, though such regulation requires to be supplemented by auxiliary arrangements, and though the belief of some that it could be attained absolutely without any waste has not been completely realised, still by availing ourselves of this feature we are enabled to control electricity with a facility and under conditions which otherwise would be unattainable.

The Hopkinson invention consisted in associating with an arc or glow electric light circuit employing alternating currents, a variable inductive resistance. This in one form was made by coiling a ribbon of thin sheet iron into a ring form, the different layers being separated by an insulating layer, and then by winding a number of coils of insulated wire on this ring, their adjacent ends being connected with plates between which contact plugs could be inserted, so that any number of the coils could be introduced or cut out from the circuit. Another form embodied the same principles, but had not a closed core. This form had a horse-shoe core made of an electro-magnet formed of layers of sheet iron insulated from each other. The legs of the core are surrounded with the coils, and the said core has an armature also made of insulated layers of sheet iron. In this form the armature is clamped down; but the regulability of the appliance is attained by moving the magnet core further into or withdrawing to a greater or less extent from the surrounding coils. The form first described is in the British patent shown as being included in circuit with the two mains of a dynamo; incandescent lamps being in cross bridges between the said mains while in another figure arc lamps are in parallel circuit with mains, an inductive resistance being included in each branch for each lamp, and acting as an equaliser.

The iron core closed on itself to form a complete magnetic ring in which the lines of force are concentrated through the coil, and forced to cut all convolutions when exposed to reversals; the laminations at right angles to the currents, acting to facilitate magnetic change, to diminish hysteresis, and to prevent the circulation of eddy currents; and the insulation of the said laminations aiding in the latter function, all tend to show that this is a very highly organised appliance, and is not only well adapted to produce a very high degree of self-induction, but combines most of the best arrangements tending to that end, and it is therefore not surprising that its invention and use made a strong impression upon the electrical mind, and caused a revival of the idea that regulation on these lines was capable of being accomplished, to use the words of the patent, "without wasting energy." Without materially wasting energy would perhaps be more strictly accurate, for by its use a small amount of actual resistance coil is enabled to do the work of a very much larger amount.

I have certainly no desire to detract from the great merit of this application, but an honest chronicler has no choice, and must say what has been done, and it must therefore be stated that inductive resistances and other self-induction appliances had long been used both experimentally and commercially; no doubt often with but an imperfect conception of their mode of operation.

\*Poggendorff's researches into the action of induction coils disclose a remarkable state of affairs for so early a date. These show that one induction coil was employed to send a current through the secondary helices of two others. The first coil thus acted as an alternating generator, and the two others as inductive resistances.

The primaries of two induction coils were connected in parallel and also in series at different times. When, to quote Poggendorff's own words, "two instruments (induction coils) A and B, were so combined that the current traversed the two primary coils one after the other, the induction coils (secondaries), however, were separated, and A was allowed to give sparks, whilst B remained unclosed and without a soft iron core; the

† Sturgeons Annals, Vol. I., pp. 290-302.

\*Poggendorff's Annalen, Vol. XCIV., p. 2, and London and Edinburgh and Dublin Phil. Magazine, 1855, Vol. X., 4th series, pp. 136-137.

introduction of the latter into B, weakened the sparks of A, and the subsequent metallic closing of B reproduced their former strength."

The proper arrangement of induction coils is then discussed, and whether the primaries should be connected in series or in parallel circuit. It is shown that the latter way is the proper one, and why. Then the paper goes on to say; "With respect to the cause of these phenomena, it is no doubt to be sought in the extra or inner induction current. The outer induction current, which is produced by breaking the inducing current, has the same direction as the latter; whereas the extra current, which is at the same time excited in the induction wire, whose tendency is to weaken the first induction current, and the more so the stronger the extra current, which latter is especially strengthened by the soft iron core.

"Consequently, when the primary coils of A and B are connected one after the other, it is clear that the insertion of the soft iron core into that of B will strengthen the extra current in that of A, and therefore weaken the induction current of the latter instrument.

"By connecting the instruments side by side, a closed circle is at once formed by them, and the extra current produced by the insertion of the soft iron core into B acts against that in A, and may, therefore, when both are equal, completely neutralise it, when the outer induction current of A will necessarily be strengthened.

"Without the circle formed by this combination, i.e., in the wire leading back to the voltaic battery, the two extra currents act of course in the same direction, and strengthen one another, in consequence of which the sparks at the current breaker are still very active."

These considerations of Poggendorff show that even at this early period a great flash of light was thrown into the darkness, which hitherto had obscured the reactions of self-induction, and though we have largely failed to use that light until quite recently, this is chiefly attributable to the same oft-recurring reason, that there was really little call for it; hence it was soon hid under the bushel of the results of research on other subjects of more immediate interest.

The statement which I last quoted brings me again to the application by Fizeau of the condenser as a shunt to the vibratory brake, and to its operation.

\* As shown by Lord Rayleigh, the condenser operates by producing electrical oscillations, and in its action the spark at the contact breaker is greatly decreased, and the spark between the secondary terminals greatly magnified, because at the break the condenser is virtually an inductive reservoir, being an electrostatic shunt. And being an electrostatic shunt, the energy it momentarily absorbs is returned reversely to the primary circuit, just as in the discharge of a secondary cell, and increases the inductive variation in the secondary circuit during the brief period of time immediately after the break. And as the electromotive force in the secondary is thus exalted, it is not difficult to see why the condenser increases the sparking distance.

As early as December 6th, 1862, a patent for cable working, No. 3,453, was taken out by C. F. Varley, which describes the use of a self-induction resistance. This patent says: "A second circuit from the cable to the earth, independent of the receiving instrument, is formed by means of a resistance coil with a large iron core. It may be advisable to connect the cable to earth through an induction coil, consisting of a large bundle of iron wire, surrounded by a long length of fine wire, the action of which is as follows: On reversing the battery connections, the induction plates (condenser) and battery combined, send a short impulse into the cable, which divides; one portion into the cable, the other through the induction coil to the earth. At the first moment, the iron of the core opposes the passage of the current, consequently during the first instant of time nearly the whole force of the current is applied to the cable. As the iron becomes magnetised to its maximum, this opposition ceases, but the plates have been charged in the opposite direction, and there is no longer any current passing from them into the cable to maintain the magnetisation of the iron; the demagnetisation of which induces a current in the coil and discharges the cable. In this way each impulse is followed by a short impulse in the opposite direction. One of the figures of the patent shows that the wires of the core are made long, and are turned back on all sides over the wire of the coil, so as to entirely encase it. This feature was in conformity with a previous British patent, No. 3,059, of 1856. The arrangement, however, clearly shows a use of a self-induction coil as a current controller, and indicates the function of a large iron core.

We next find the counter E.M.F. of self-induction coming into use in connection with fast telegraph systems. Arrangements for its use are shown in the United States patents granted to Mr. Edison. These are, respectively, No. 135,531, of February 4th, 1873; No. 141,773, of August 12th, 1873; and No. 147,313, of February 10th, 1874.

The first and second disclose a shunt circuit, including an electro-magnet connected round the receiving instrument of a chemical telegraph. The first also shows a leak to earth from the line, which leak includes an electro-magnet. In both cases the object is to utilise the discharge current developed by the electro-magnet in the regulation of the operation, and to produce sharp and clear signals.

The third describes the use of electro-magnets in shunt circuits

round the transmitting and receiving instruments of an automatic telegraph system, and is said to be an improvement on the first. A number of electro-magnets are shown, and by means of a switch one or more of these may be introduced. In other words, the inductive resistance is here adjustable, and is operated by breaks, not by reversals.

British patent, No. 3,935, November 14th, 1874, to Alexander Melville Clark for a chemical copying telegraph, uses induction and other coils to clear a line by the self-inductive counter E.M.F. By the decrement or cessation of the impulse (as the patent states) the strongest depolarising effects are produced, and the line is successfully cleared.

Next come four other patents to Thos. A. Edison. These are U.S. patent, No. 163,243, of September 28th, 1875, for an automatic telegraph. This, as in the previous cases, employs an electro-magnetic shunt.

U.S. patent, No. 168,385, of October 5th, 1875, duplex telegraph. This is an excellent example of self-inductive regulation. The counter E.M.F. is developed from electro-magnets in a changing electric circuit, and the coils have cores closed on themselves.

The next two, No. 173,718, of February 22nd, 1876, for automatic telegraphy; and No. 178,221, May 30th, 1876, Duplex Telegraphy, involve no new principles, and are like the preceding ones.

\* Much information regarding the subject, and further examples of its practical application, can be found in a particularly able paper on "Shunts," read by William H. Preece, before the Society of Telegraph Engineers in 1887. The subject of the counter E.M.F. developed in electro-magnets is discussed, and the increase of the same, when the iron core is endless, is determined and pointed out; a good many instances of the practical uses of the self-induction shunt are described.

U.S. Patent, No. 207,724, of September 3rd, 1878, granted to Thos. A. Edison for a duplex telegraph, shows an electro-magnetic coil and closed magnetic circuit core placed in each branch of a Wheatstone bridge duplex telegraph, to counteract by its counter E.M.F. of self-induction the discharge of the electro-magnets in the bridge circuit. In Culley's Handbook of Practical Telegraphy, London, 1878, pp. 303 to 304, also pp. 305 and 411, the regulation of currents by inductive resistances is considered.

In the first instance, the counter E.M.F. of an adjustable series of electro-magnetic coils is used to delay the discharge of a condenser in a duplex system. This is closely analogous to the function of the Hopkinson device, and is very suggestive. The reference on page 305 states that "static discharge can be entirely compensated for by the use of an induction coil, or a series of electro-magnets, instead of a condenser."

U.S. Patent, No. 227,039, of April 27th, 1880, to Muirhead and Winter, for a quadruplex telegraph, describes electro-magnetic shunts for reversing keys and relays, which are to counteract, by their discharges, electrostatic retardation. The specification says: "The electro-magnets may be of the well-known closed horseshoe form, or they may consist of a single rod of soft iron, with flanges of soft iron, and a cylindrical casing of iron closing over the wire, and connecting magnetically flange with flange.

U.S. Patent, No. 231,904, September 7th, 1880, to Joseph E. Fenn, duplex telegraph, uses an electro-magnetic generator of counter E.M.F. in the line circuit to counteract effects of discharge. It is made with a closed magnetic circuit, a separate coil being on each leg of a multiple pole core; several of these poles are made with yokes, and the combined yokes can be made magnetically continuous or discontinuous at will by means of iron plugs, which can unite the different sections of core.

A book published in 1880, by Louis Schwendler, and entitled: "Instructions for testing telegraph lines, and the Technical Arrangements of Circuits," Vol. II., pp. 144-147, gives a description of an electro-magnetic shunt and its operation. It is made like an ordinary electro-magnet, but has an adjustable wedge-shaped armature in contact with the cores. This, of course, operates by utilising the counter E.M.F. of self-induction, which develops currents that circulate through the shunt, and sharpen the signals.

In telephony, also, as in other fast systems employing rhythmic currents, the counter E.M.F. has by no means been idle. As in telegraphy, our early acquaintance with it was an unpleasant one. Many of the earlier telephone lines connected with a number of stations, and at each station there was, of course, an electro-magnet to operate the call. In some cases this was a telegraph relay, and in other cases a bell magnet. But in either case it was found, as, indeed, might have been anticipated, that the telephone currents had a decided repugnance to pass through the intervening electro-magnets on their way from one station to the other. To quote the graphic words of one of the patentees of devices intended as remedies for this trouble, it was found that electro-magnets were, to a large extent, "opaque to telephone currents."

Of course this is due to self-induction. The resistance of the line or the magnet coils had little or nothing to do with it. The convolutions, however, had, since it is clear that the electromotive force of the self-induction was proportional within certain limits to the number of convolutions.

The same difficulty appeared also in exchange work, where between any two connected lines was interposed an annunciator, to give from either end station a disconnecting signal. Several

\* Phil. Mag., Vol. XXXIX., p. 428, et seq.

\* Journal of Society of Telegraph Engineers, London, 1877, pp. 40-69.

devices have been suggested for the removal of this difficulty, and some of them have been patented.

Elisha Gray shunts the several interposed magnets by condensers: *vide* United States Patent, 203,264, of May 7th, 1878.

F. W. Jones, attacking the same difficulty, shunts the interposed magnet by a non-inductive resistance controlled by the armature of the signalling magnet. See United States Patents, 238,399, of March 1st, 1881, and 238,912, of March 15th, 1881.

Other devices have also acted to shunt the bell or annunciator magnets in different ways; and still other suggestions have been to surround the iron core with a brass sleeve, or with a closed circuit consisting of one layer of insulated wire; but these last, while certainly reducing the retardation, reduce also the magnetic power of the appliance. And there is no remedy so effectual as the absence of the interposed electro-magnet.

The service rendered by self-induction in telephony, and that which still may be expected, fortunately will probably outweigh the ills which it introduces. In many switchboard installations for metallic circuits, the supervising telephones are looped or bridged across between the two conducting links which unite one of the two metallic circuits with the other, and their self-induction prevents a material loss of current. Where from some condition of the service, such, for example, as the requirement of supervising both metallic and earth return circuits at the same switchboard, it sometimes becomes necessary in bridging the telephones to attach an earth branch to the connecting link on one side of the instruments; in this case it has also been found necessary in practice to place coils containing iron cores on the other side of the earth branch, so that not only the resistance, but also the self-induction, may be balanced.

It has also been ascertained that many telephones can at different stations be placed across from one wire to the other of a metallic circuit, without any perceptible diminution of the effect at any one of them. This is one of the most important results of self-regulating attribute of self-induction.

Perhaps, however, the most valuable instance of turning an electrical enemy into an electrical ally, is the way in which by the proper use, construction, and arrangement of electro-magnets, a plurality of either telephonic, or partially telephonic and partly telegraphic messages, may be transmitted over the same circuit at the same time.

The pioneer in this kind of work was C. F. Varley, who as early as 1870 took out a patent, No. 1,044, in England, for a combined simultaneous ordinary Morse and harmonic Morse transmission over the same wire; in this system the straight Morse was worked through electro-magnets, while the harmonic branches were led off from the main line from points outside of the electro-magnets.

Carrying on this line of invention, Mr. Van Rysselberghe, of Belgium, and Dr. Roseburgh, of Toronto, Canada, have worked out systems whereby telegraphy and speaking telephony can be at the same time operated over the same circuit.

Since, however, there is enough in either system to fill up a paper devoted to them exclusively, and since this paper is already too long, I find it impossible here to describe them in detail, reserving this possibly for some future occasion.

Self-induction has also been caused to aid in eliminating the disturbing results of extraneous induction caused by parallel circuits, as in the United States patent of Mr. Edison, No. 203,019, of April 30th, 1878, where a telephone circuit is freed from external influences by combining it with an induction coil connected with the disturbing circuits in such a manner that the direct disturbances received in virtue of the parallelism of the contiguous circuits is neutralised by an equal and opposite induction received also from them through the induction coil. This, however, is not a practical expedient.

Closely analogous to the self-inductive regulation of which I have been speaking, is that upon which the efficiency of an electro-motor depends. This was first observed by Jacobi,\* who says:—

"Experimenting on the magnetic force of a bar of soft iron, I sometimes found considerable differences for which I could in no way account. I was curious to know if these differences proceeded from the nature of the iron, or from the weakening of the electric current produced by a voltaic pair of half a foot square of surface. For this reason, I placed in the circuit a galvanometer so distant as not to be affected by the direct magnetism of the bar. I was much astonished to see the needle recoil on placing the armature, and advance on removing it, for it was the first time I had known the double quality of the connecting wire, viz., that of constructing the voltaic current, and at the same time representing an ordinary wire subject to the action of a magnet in motion. The spiral producing a magnet by the voltaic current is at the same time a magnetic electrical spiral in which a magnet is placed.

Hence the solution of the uniform velocity of the magnetic machine. For being set in motion by the magnetising power of a voltaic current, it represents simultaneously an apparatus composed of magnets in motion, and capable of producing a magnetic electrical current in a direction opposite to that of the voltaic current."

Jacobi, in a subsequent paper, practically elucidated the principles of the operation of counter E.M.F. in electro-motors, even as now understood, although he possibly did not state them as we now would. But he clearly showed that a motor may be regarded as a dynamo acting to develop an electromotive force, opposite in

direction to that acting upon it, *i. e.* That the resultant force was of course  $E - e$ , and that this, together with the resistance of circuit, determine the strength of the current. That the motor utilises  $c e$  of the electrical power supplied  $c E$ ; and he furthermore showed that the power developed by the motor,  $c e$ , is at its maximum when  $e$  equals one-half  $E$ .

It may be thought by some that, considering the title of the paper, the principal utilisation to which I have referred, viz., the use in regulation of systems of alternating currents operating on-verters should have been discussed. It does not seem to me that it is necessary; this has often been done, and will again often be done by others much more competent than myself to handle the subject. But it does seem right that one should be found to give due credit for those who in the same line of thought are "not lost, but gone before," and I am glad that I am in a position so to do.

There seems little need for me to cite any more instances, showing that, like nearly all new arts, the art of regulation by means of self-induction and of otherwise usefully employing the counter E.M.F. due thereto, is not quite new, and that while we can congratulate ourselves upon the achievements of the present, we should not fail to respect the foundation layers of the past, for, of a truth, there were giants in those days.

## ABSTRACTS

### OF PUBLISHED SPECIFICATIONS, 1889.

6867. "Improvements in holders for incandescent electric lamps." C. RICHARDSON and G. HILL. Dated April 24. 6d. Claim:—In an electric incandescent lamp-holder or other like fitting, the use of a piece of insulating material of the form of a cylinder with two deep flats, one on each side, or further to be described as shaped in the nature of two washers joined together by a stout web, substantially as shown and described.

7774. "Improvements in means for supplying electric current to road vehicles, boats, and the like." R. C. SAYER. Dated May 4. 8d. In the case of tramcars and vehicles on public roadways, or canal or other boats, the electric current to work their motors is conveyed to them by means of similar line conductors explained in patent application No. 3,487, A.D. 1889, but the wheels are to be inverted and the conductors carried above the vehicles or boats, the latter (the conductors) are to be deepened to act as longitudinal continuous girders when desired for long spans, and reduced to compound wires or cables when desired for short spans or to prevent obstruction. 3 claims.

7808. "An electric alarm attachment for pressure, vacuum, speed, and other gauges." A. JULIAN. Dated May 10. 6d. Claim:—An attachment to pressure, vacuum, speed, and other gauges for sounding an alarm by means of electricity.

8453. "Improvements in regulating electric currents." W. M. MORDEY. Dated May 21. 8d. The apparatus consists of three principal parts, the relay, the regulator, and the resistance or other device required to be moved, controlled, or varied. The relay consists of a core and solenoid arrangement preferably comprising two fixed hollow wooden bobbins wound with wire, and placed vertically and parallel, and having a U-shaped core freely suspended and entering the bobbins from below. The core is of laminated iron or iron wire, to increase its sensitiveness by reducing reactions to a minimum, especially when used with alternate currents. This core controls a contact-maker of any suitable form. 3 claims.

8493. "Improvements in automatic cut-outs for electrical circuits." W. J. STARKEY BARBER-STARKEY. Dated May 22. 8d. The inventor includes a small dynamo or magneto-electric motor in a high resistance shunt from the dynamo or mains. By means of stops or other devices he limits the possible angular motion of the armature of this electro-motor so that it may not rotate continuously whilst its circuit is closed. The spindle of the armature is geared or connected with a switch or device, such as a mercury or brush contact, for opening and closing the main circuit. 7 claims.

9096. "Improvements in telephonic switchboards." H. F. JACKSON and D. SINCLAIR. Dated June 1. 8d. In lieu of a switchboard having the portion which carries the line jacks placed in a vertical position over a single switch table carrying the usual indicators, cords, switches, and other accessories used by the operators in calling and making connections between subscribers, the inventors form a duplex switchboard in which the part carrying the line jacks is laid horizontally between switch tables on two opposite sides, and each provided with indicators, cords, and other usual accessories, so that operators placed at both switch tables may use the same board to make connections to all the subscribers from any of the two different sets of subscribers whose calls they attend. 4 claims.

9182. "Improvements in apparatus or devices for switching or diverting electric currents, more especially intended for use with telephonic circuits." A. GRAHAM. Dated June 3. 11d. Has more especially for its object to provide an arrangement of switching board and devices for telephonic circuits, whereby they can be used for switching or diverting the currents, whatever the arrangement of the circuits may be. 5 claims.

\* Sturgeon's Annals of Electricity, 1837, Vol. I., pp. 408-419.

9183. "An improved exciting liquid for electric batteries." Dated June 3. 4d. M. SÜSSMANN. Claims:—1. An exciting liquid for electric batteries, consisting of a solution of ferric chloride to which zinc chloride is added. 2. The addition of the chloride of that metal of which the electrode consists to the solution of the ferric chloride.

9294. "Improvements in and relating to dynamo-electric machines and electric motors." H. H. LAKE. (Communicated from abroad by C. S. Bradley, of America.) Dated June 4. 1s. 1d. Consists in an electric motor or dynamo-electric machine of any class to which the invention is applicable, having its field magnets energised by currents induced in the mass of the magnet itself as distinguished from the magnetism produced in the field magnet by a current or currents circulating in insulated conductors wound upon the magnet. The invention further consists in the construction and arrangement of parts for the above ends, and the combination of devices used in starting and operating the motor. 22 claims.

9713. "Improvements in electric conductors." J. G. LORRAIN, (Communicated from abroad by La Société d'Exploitation des Câbles Electriques, Système Berthoud, Borel, et Compagnie, of Switzerland.) Dated June 12. 6d. The inventor takes a core of any of the usual forms, and upon this he winds in the same direction of progressive revolution two ribbons of paper or the like, one of which ribbons is half a width in advance of the other, so as to effect what is known to engineers as "breaking joint." Over the covering thus formed he winds a second serving consisting as before of two ribbons arranged so as to break joint: but in the case of this serving the direction of winding is the opposite to that of the winding of the first serving. In this manner he proceeds until a sufficient number of servings has been put on to give the desired thickness of dielectric. 3 claims.

9723. "Improvements in grids or containers for the elements or plates of secondary batteries, and moulds to be used in their manufacture." THE ELECTRICAL POWER STORAGE COMPANY and P. J. REA. Dated June 12. 8d. According to this invention a mould or chill is provided for the casting of secondary battery grids or containers for the active material or materials to be rendered active, by means of which the grid is so formed that the material with which the holes therein are to be filled is not liable to split or fall away. 2 claims.

10440. "Improvements in holders for incandescent electric lamps." H. BAYLEY. Dated June 27. 8d. Has for its object simple means for facilitating the attachment and disconnection of the head or cap of a holder for an incandescent electric lamp, and the socket or case thereof for the purpose of wiring the holder. 3 claims.

10556. "An improved manufacture of flexible electric cable." W. E. GRAY. Dated June 29. 6d. The inventor provides a metallic core consisting of a bundle of fine copper wires slightly twisted; this he covers with insulating material, then braids over the insulating material in the usual way. The cable thus far made is enveloped in a flexible metallic sheathing composed of, say, twelve strands of steel or iron wire, each strand being composed of, say, seven wires, No. 20 gauge, specially compounded. This flexible sheathing is covered with a suitable tape, and after coating this with a preservative compound, the cable is completed by braiding upon it a strong covering of hemp or jute. 1 claim.

10699. "Apparatus for automatically regulating the potential in the conductors for two or more sets of electrical lamps." SIEMENS BROTHERS AND COMPANY. (Communicated from abroad by the firm of Siemens and Halske, of Berlin.) Dated July 2. 8d. Relates to means of automatically regulating the potential in the conductors for two or more sets of electrical lamps, when two or more sets of lamps are connected in series, and the conductors are so arranged that all of them, except the two end ones, are common to two sets of lamps. 1 claim.

10933. "Improvements in electro-motors." M. VON DOLIVO-DOBROWOLSKY and the ALLGEMEINE ELECTRICITÄTS-GESELLSCHAFT. Dated July 6. 8d. Claim:—In a secondary electric machine the combination with a magnetic field of an armature composed of an iron body of rotation, bars, strips, or wires of copper arranged transversely to the direction of rotation of the machine, and also transversely to the lines of force of the magnetic field and copper conductors, whereby the said bars, strips, or wires are connected together at both ends, substantially as described.

11049. "Improvements in dynamo-electric machines, in part applicable to electro-motors." J. J. WOOD. Dated July 9. 1s. 1d. Consists, firstly, in an improved method of winding the armature, whereby the short-circuiting of the armature coils within themselves is prevented; and, secondly, in improved means for effecting the automatic regulation of the current generated, in order to maintain it at a uniform volume. 3 claims.

11832. "Improvements in junctions or couplers for electrical conductors." F. R. DOLBY. Dated July 25. 6d. The inventor forms one or more parts or all the parts of the couplers, so that a current of electricity may be passed round them or through them in order to magnetise such part or parts, which will be made of some magnetisable material, the object being to cause the parts of the coupler to be attracted to one another, and so cause a grip, and at the same time by such pressure to make good contact for the passage of the current or currents through the conductors thus joined together. 2 claims.

12773. "Improvements in apparatus used for electric railways." F. WHEELER. (Under International Convention.) Dated January 14. 8d. Consists in constructing a trolley, which, when applied to line conductors suitably supported, cannot, without intention, be removed therefrom. To attain this object the inventor employs in connection with two line conductors or wires, supported at intervals by brackets, the arms of which extend from the centre outward, a trolley, the wheels or rollers of which are supported from the outside of said conductors. 6 claims.

12901. "Improved means for supporting and separating the plates of electric accumulators." R. E. B. CROMPTON. Dated August 15. 6d. The plates in the cell rest on two lines of supports, each line of supports consists of two bars placed at convenient distance apart, and notched on their upper surface to receive the plates in alternate order, so that the whole of the positives rest on one bar, and the negatives on the other bar. When viewed from the side the edges of these bars are cut away between the notches, so that the alternate plates pass over them and clear of any possible contact with them. The connecting pieces which separate the two bars in relation to one another are so arranged that in every case vertical surfaces only, on which no deposit can rest, are interposed between the notches which carry the two sets of plates. 3 claims.

13322. "Improvements in the means or apparatus for transmitting electric signals." E. J. P. MERCADIER. Dated August 23. 8d. Consists of:—1. A vibrating body of suitable form, as, for example, a spring plate or a diapason, the vibrations of which are maintained electrically by the complete or partial automatic interruption of an electric current traversing one or more electro-magnets situated in the vicinity of the vibrating body. 2. One or more coils or bobbins, with soft iron core placed in the magnetic field of the electro-magnets, and connected together in series or for quantity. 3 claims.

17088. "Improvement in means for operating mechanical devices electrically, specially applicable to electric meters, electro-motors, electric lamps, and electric cut-outs." W. E. IRISH. Dated October 29. 1s. 1d. Consists in the utilisation of a rod or strip of metal, composing an integral part of the circuit, and affected to expansion or contraction by the passage of the current to operate devices for switching, regulating, and measuring the electrical current, in connection with suitable connecting mechanism. 29 claims.

20660. "An improved electric signalling apparatus." J. O. WINCKLER. Dated December 23. 6d. The object of this invention is to enable miners during their ascent or descent of the mine to give electric signals to the engineer from the cage or lift, as to whether he is to stop, lower, or wind up, also to indicate to the engineer the speed of travel of the cage by electric bell signals. 1 claim.

## CORRESPONDENCE.

### Prof. Elihu Thomson's Alternator.

This machine possesses some interesting features. But is not the theory, as put forward by the American journals, erroneous? Are there any lines of force moved, except in so far as they are brought into existence and made to vary in intensity? It seems to me that the production of current in this case essentially depends on the inductive effect arising from change or variability of magnetism. The variability—for there is no absolute change of magnetism in any part of this machine—is caused by periodically opening and closing a series of magnetic circuits. If a longitudinal section of one half of the machine be considered, it will be seen that the magnetic circuit so formed is alternately closed and only partially opened by the star-shaped armature, so that the resultant current would be proportional to difference between iron and air as magnetic mediums; the break in the magnetic continuity making the necessary magnetic change; and as this break is only partial, depending on the depth of the cavities between the projections of the star-shaped armature, there is neither cessation or reversal of magnetism. Would it not be more correct to call the machine a mechanical transformer?

E. L. Voice.

August 23rd, 1890.

We notice in your publication of August 15th an account of Prof. Thomson's latest dynamo.

It is apparent from the enclosed description of Pyke and Barnett's machine, of which we hold the patents,

that there is a considerable similarity, although their patents cover far more than Prof. Thomson's in the equalisation of the field magnets. The poles of Prof. Thomson's machine have not so much chance of obtaining saturation as ours, as they are only partially covered for an inappreciable period of time. When the inductors are between cogs, the field is partly varied, but in Pyke and Barnett's patents the field is equally closed, so that there is less strain on the inductors, and less pulsation of the shaft, and no loss due to heating, whereas, in Prof. Thomson's machine, it is apparent that there is considerable loss from heating in the field, more particularly the inner revolving part of the same; but in Pyke and Barnett's there is ample space for ventilation.

Pyke and Harris.

August 26th, 1890.

#### Electric Traction.

We have your issue of August 1st, and note, on page 128, your article about our company, and what our cars are doing at Beverly, Mass. Yes, you are "gravely assured" that every word in the article in the *Boston Post* is as stated; and we further believe the last six lines of your article to be true. We have *proved* every point and stand ready to, and are perfectly sure we can, convince anyone of all these statements. If we have all this it is worth looking into, is it not? We advise you to do so. We hand you herewith cuts of our trucks, cars, power house, &c.

Union Electric Car Co.,

By JOHN H. ALLEY, Vice-President.

Boston, August 11th, 1890.

[We can only insert this letter and advise our readers, especially Messrs. Holroyd Smith, Reckenzaun, Elieson, Lineff, &c., to refer back to our issue of August 1st.—EDS. ELEC. REV.]

#### Electrical Endosmosis or Cataphoric Medication.

I am sure that now a prominent electrician like Mr. Edison has spoken on this subject, it will receive the attention it deserves. But the subject has really been before the medical profession for a considerable time, first, as a well-known physiological experiment, and for twelve months at least as a matter of practical application by myself, and doubtless by others.

I showed cases of rheumatoid arthritis and other diseases, under treatment by this method, at a lecture given to my mixed class of medical men and nurses at the Institute of Medical Electricity on November 5th, 1889; I spoke on the subject at the December meeting of the Brussels medical graduates (1889), and on December 11th of the same year I published a paper in the *Medical Press and Circular*, giving in some detail my plan of using the process.

I hope shortly to publish a *series* of cases treated by cataphoric medication, though I have hitherto refrained from doing so, inasmuch as it is unwise to draw conclusions from a single case of any particular disease, or even from a limited number of such cases. I have preferred to wait until circumstances enabled me to bring forward a sufficient number of results.

Arthur Harries, M.D.

August 25th, 1890.

#### Cable Testing.

Considering my youth, inexperience, and past discourtesy, I ought to be deeply grateful that the editors of so learned and scientific a journal as the *ELECTRICAL REVIEW* should have sacrificed more than two pages of their invaluable space to my mental improvement; but, strange as it may appear, I recognise in this action less

of good nature than of a desire to find material to fill the columns of their paper.

Clever as the editors of the *ELECTRICAL REVIEW* have always shown themselves at forecasting events (notably in the case of the Marchant engine, which was to "revolutionise the electric lighting industry"), their prophecy that I should regret having sent them my communication has, contrary (?) to precedent, not been fulfilled, for I am still so deluded as to think that I have not described a method of testing which is so very commonly known, or so ancient as some people would have me believe.

On first seeing such well-known names as Kempe, Webb and Varley appended to letters stating the absolute antiquity of my method, remembering Virgil's sententious lines,

Sum pietate gravem ac meritis si forte virum quem  
Conspexere, silent arrectisque auribus adstant,

I felt inclined to abstain from further comment; but after carefully perusing their letters, I have come to the conclusion that a different course is open to me.

Mr. Kempe says that the method I have described is old, and so obvious as not to require description in any text-book.

I cannot see that my method is any more obvious than Warren's method, yet the latter, which has the great disadvantage of necessitating the cutting of the outside sheath of the cable a large number of times for each fault localised, and which, consequently, is not so expeditious as my method, is described at considerable length in Mr. Kempe's and other text-books. Moreover, it seems strange that in the columns of "The Philosophical Magazine," so recently as 1879, attention should have been drawn to Warren's method, when, according to Mr. Kempe, a method was then already very generally known, which involved no cutting of the outside sheath of the cable.

I have very little to say to Mr. Varley's letter beyond remarking that he has entirely missed the point at issue. The method which he describes, and which, by the way, he evidently considers reflects considerable credit upon its inventor, despite its being, according to Mr. Kempe, so obvious as to need no description, is of course perfectly applicable to G.P. covered wires. If, however, the leads had been covered with tape or felt, the method which Mr. Varley describes would have been of no use.

Another correspondent, whose name is withheld from publication (a procedure which I imagined was contrary to the rules of the *ELECTRICAL REVIEW*), refers me to Culley for a description of the original method of fault-finding by passing lead through an insulated trough. This gentleman seems to think that my method, and the one described in Culley, are identical. If he will take the trouble to read a little further, he will find that the above is not the case, for Culley, having described the method of testing with a trough, goes on to say: "To find a fault in a very highly insulated sheathing, *covered with a good conductor*, Hooper's material, for instance . . . the tape is carefully removed over a space of 6 inches," &c., describing, in fact, Warren's method, to which reference has already been made. My test is certainly not indicated in Culley, as special mention is there made of a method to be adopted (involving cutting of the outside sheath) where the faulty cable is insulated with sheathing covered with a good conductor.

The copy of Kempe's "Electrical Testing," which is in my possession, contains no account of Mr. Jacob's method; the latter has, however, been described to me, and, so far as my memory serves me, I believe it to differ from my own in several essential points. Should, however, this not be the case, my position will be considerably strengthened, for it appears that Mr. Kempe has thought it worth his while to publish this test in his latest edition of "Electrical Testing," which he surely would not have done had the method been so obvious, so ancient, and a matter of such common knowledge as he, in his letter, states it to be.

H. Cuthbert Hall.

ELECTRIC LIGHTING AS APPLIED TO  
RAILWAY SERVICE.

To those who have noticed the rapid extension of the electric light in America, and its ready application, amongst other institutions, to railway requirements, the apparent indifference of railway companies in England to its advantages must appear somewhat remarkable. Again and again we are tempted to ask, is it indifference or is there any other reason? We do not think England's railway managers, or those who are more directly responsible for the despatch of business, are indifferent to the requirements of their service. They are men specially selected for the onerous posts which they invariably fill with much credit, for their fitness, their ready business qualifications, and their keen appreciation of the value of time and money. We have seen that the light is employed in the interests of certain companies, so that it is clear its advantages are not kept under a bushel by the electrical departments of the several services. Is it that our large railway corporations are so conservative in principle that they cannot sever their connection with oil and gas? Or is it that the cost, being probably more than that now paid for illuminating a given space, is so much less than that required for the electric light? We are inclined to think this is nearer the point. In many instances we know how apt we are to look at any expenditure which may exceed that which we for the present incur. Railway companies now light a goods shed or a marshalling ground for so much. To establish the electric light will call for a special outlay—perhaps of a sensible sum of money. It will cost in maintenance, possibly, more than is paid for the gas as now used? Where is its advantage?

Those who look at the question in this manner will find in it no advantage; but there is another standpoint from which it may be viewed. We have heard it stated that the cost of a fairly heavy installation for the purpose of aiding the working of an important and

somewhat circumscribed goods yard of a London railway depôt was entirely recouped by the suppression of the amount of losses incurred for goods of which the company was annually robbed. Whether this is so or not, we know it to be a fact that so greatly has, and does, the form of lighting now employed aid the working of the yard, that nothing would induce the officials to part with it; whereas, before the work had to be done with a light which practically rendered the darkness more visible, it is now carried on under a light which at all critical points affords an illumination as nearly equal to daylight as artificial light can approach. Trains arrive. The shunter calls for certain roads. Standing near his train, the light shows him the instant the points are set and the road is made. The signal is given to the driver, and in a moment the vehicles for that road are on their way and another road is being asked for to be used in a similar manner. Thus, in ten minutes or a quarter of an hour, is the marshalling or the distribution of a train dealt with, as against a probable hour under the old method of hand and gas lamps. Nor should the question of safety to those engaged in the work be forgotten. Custom, it is said, brings with it contempt. The man who is careful as a new comer, often becomes indifferent to danger the more experienced he grows. With an imperfect light men must, at the best, be always on the alert. With a light which renders clearly visible the approach of vehicles the mishap of a moment should not occur.

Another case, illustrative of the advantage of a sufficiency of light to enable work to be dealt with expeditiously, comes to our memory. The traffic of a large goods depôt, within a hundred miles of St. Martin's-le-Grand, had so increased, that it was found impossible to deal with it during the night in sufficient time to get the trains out before the morning residential traffic took possession of the line. The goods trains were fairly stopping the passenger traffic, and there was no apparently possible way of meeting the difficulty except by increasing the loading accommoda-

tion of the goods station, so as to admit of more vehicles being loaded at a time. This, at the time, was not possible, for the reason that money could not procure the land; had it, however, been procured this form of redress would have involved a combination of the inconvenience till the additional accommodation had been provided. We believe it was due to the ready resources of the goods manager of the line, to which our remarks refer, that the company was delivered from the dilemma in which it was thus placed. It occurred to him to throw more light into the goods sheds and yards, and this he did with no niggard hand. The loading stages and the shunting grounds were, practically, flooded with light. The men worked with freedom; hand lamps were set on one side. The time occupied in handling them was bestowed upon the actual work of loading and unloading the goods. The desired end was secured. The trains were disposed of to their time, and the traffic restored to its normal regularity.

We give these as points in fact, where most important advantages attended the introduction of the electric light, and where, in one instance, it is probable a large outlay for buildings and land was, at all events postponed, if not absolutely saved. They are facts which are probably as well known to the railway companies as to ourselves; and it cannot be doubted that equal advantage might be secured by its employment elsewhere. That its employment effects a saving in labour—in men's time; that it aids despatch; that it is an efficient factor in the suppression of accidents, we think must be clear to all who care to consider its use in the sense in which we have instanced its utility. That it actually costs more than the existing outlay for a very poor and minor light, does not condemn it as more costly in the end. Take into consideration the issues secured, and we question if the advantage is not so greatly on the side of the electric light as to utterly debar any comparison with other illuminants.

Electricity has been of the greatest service to railways. It is difficult to conceive at this moment how the railway work of the country could be dealt with without it. Certain it is that an enormous outlay must have occurred in duplication of lines had not electricity aided in the regulation of the traffic. And it is equally certain that electricity will year by year, and day by day, prove itself, if well and judiciously handled, of still greater service. So many are its applications, so readily does it adapt itself to every requirement, and so exact is its proportionments when in operation, that it readily presents itself to the service of all who desire to avail themselves of it. In the illumination of railway stations, goods depôts, goods yards; in the marshalling of goods trains and in their distribution; in the lighting of passenger trains; in welding, and, possibly, at no distant date, in the operation of machinery now worked by hydraulic power, we see a field of utility great alike to the community at large as, more immediately, to the railway interests. Shortly we may see a large portion of the City of London illuminated by the electric light. It seems but a few years since our attention was drawn to the subdivision

of the arc, and now that we are arranging for the permanent lighting not only of our metropolis, but of many of our most important towns, we may fittingly consider what has been the progress on railways?

Practically, railways have done very little. Some few of our London stations—Paddington, Cannon Street, the London, Brighton and South Coast at Victoria, the London and South Western at Waterloo and Nine Elms, Cannon Street, Charing Cross, Liverpool Street, and the Midland at St. Pancras—have been, and may, we presume, now be regarded as permanently lighted. But out of London we find little doing. At Glasgow we have the St. Enoch's, Glasgow and South Western Station and Hotel, the Central Station and Hotel, the Grangemouth Docks (both Caledonian), the Waverley Station, Edinburgh, and the Underground Railway, Glasgow (North British), illuminated by the same means.

In the provinces, Bradford stands forth as a brilliant exception. The Midland Company has recently built a very fine and commodious station here, to which there is tacked on a charming hotel, replete with all the advantages and comforts of the present period. The whole of this station, booking offices, waiting rooms, approaches, parcels office, cloak room, and all other offices, refreshment rooms, as well as the hotel, are lighted by electricity throughout. The station, in this respect, stands unique. It is the only station, we believe, extant, which has been so equipped.

We do not know the reasons which have induced the Midland directors to thus again signalise themselves as pioneers in the application of a great and useful branch of science, but we feel that we do not stand alone in our admiration of an intelligent corporate body thus recognising and testing in an efficient and broad manner the worth of that in which they probably see a promising future. We understand that, in laying down the machinery for this installation, provision has also been made for lighting the new goods warehouse which is to be raised on the ground occupied by the old passenger station. In this installation we have hydraulic and electric machinery, with boilers, all within the same building, so that the utmost economy will be obtainable in labour.

Before leaving the subject of lighting, we must not omit to add that the Midland is also laying down, and will shortly have in operation, one of the largest arc light installations extant—viz., 150 arc lights—for the illumination of the St. Pancras goods depôt and the new goods warehouses and yards adjoining the St. Pancras passenger station.

The application of electricity to the lighting of railway trains must necessarily feel its way, but the efforts made by the Midland to solve the question bear with them every prospect of success. For some years the London, Brighton and South Coast Railway has been running trains illuminated by this means, the dynamo being driven from the axle of one of the vehicles, and the lights being sustained by one set of accumulators arranged in the same vehicle. The experiments carried out by the Midland have taken a wider scope, and have had for their object the

determination whether electricity is capable of being applied to all the exigencies of railway traffic. Thus, with respect to main-line trains, and others, which are not always coupled, *i.e.*, trains *en bloc*—each vehicle carries its own lighting power, accumulators capable, when fully charged, of sustaining the whole of the lights of the vehicle for a given period—say, six to eight hours—being provided in each carriage. So far the Midland has now had running for some time daily out of London two trains for Manchester and Liverpool, and two trains for Nottingham, Sheffield, Leeds, and Bradford; and, similarly, two trains daily from each of the places named to London. These trains, together with a local “*bloc*” train running between Manchester and Stockport, have the dynamo driven, like the Brighton Company’s trains, from the wheels of one of the vehicles on the train. We understand, however, that the Midland is now proceeding a step further, and fitting other trains, driving the dynamo direct from a small engine placed upon the locomotive.

So far train lighting by electricity has been confined to the Brighton, South Eastern, Great Northern, and Midland. With the exception of the Midland there has been no attempt to deal with trains broken up on the journey, or for slipping coaches, &c., on the way. At the same time it is worthy of mention that experiments to a small extent, and extending over a very short period, have been made by the Great Eastern and Lancashire and Yorkshire Railway Companies.

We can only hope that the experiments which have been undertaken, with so much success so far, by the Brighton, the Great Northern, and the Midland, will be pursued to that successful end which will establish so useful and so favourite a form of light for the comfort of the travelling public. Difficulties invariably accompany new applications, and in the application of electricity to the purpose in question there are, undoubtedly, many new phases to deal with. Apparently these have been, so far, so well met as to leave little doubt of ultimate and complete success.

### THE HOPKINSON AMENDMENT.

HOWEVER dry the subject matter, the perusal of a pile of statutory declarations furnishes, at times, an interesting and instructive occupation. We have read the Hopkinson Amendment Declarations once more before consigning them to the receptacle reserved for ephemeral literature, and with the evidence before us confess that we can find no fault with the decision of the Comptroller-General. The patent of the Brothers Hopkinson is for “improvements in the construction and application of induction coils,” and the patentees applied for leave to amend the above title by specifically limiting their claims to coils used “for electric distribution,” these last three words being proposed to be added to the title. The claims were proposed to be narrowed down to two, which included secondary generators having an approximately closed magnetic circuit of laminated iron—three claims for methods of regulation having been excised. The specification

appears to have been carelessly drawn up, as it contains several clerical errors, for leave to correct which application was also made. These errors are “contact” for “control,” “neutral” for “mutual,” and “perpendicular” for “parallel.” Many sincere and solemn declarations were obtained by the opposition to show that they were not errors at all but that the words proposed to be used instead of them constituted an afterthought on the part of the applicants. However, the Comptroller-General of Patents has allowed the corrections to be made, the fact that the words in question were verbal errors being perfectly clear from the description and drawings—that is to anyone not an expert witness retained by the opposition. As is well known, the expert witness can display the profoundest idiocy or the sharpest intelligence, as occasion may require. Leave to amend the title has not been granted, nor have the claims been narrowed down. The opposition sincerely and solemnly declares that such amendment would entirely alter the scope and bearing of the patent. Perhaps it would; we are not quite sure, but we don’t think so. However, as there is a doubt on the point, the Comptroller has done right in disallowing the proposed amendment. The patentees say that the application of induction coils to electric distribution is clearly implied in their specification, and that this would be understood by any person conversant with electrical engineering who read that document fairly. We say so too, for the frequently employed term “secondary generator” proves this apparatus to be included under the more comprehensive title of induction coil. But this affords no reason for allowing the amendment, and as the scope of a patent admits of more than one interpretation, if there are doubts, they had best be settled in the Law Courts. People who draw up specifications in loose fashion must be prepared for the pleasant contingency of a decision by Judge and Jury.

Electrical Nomenclature.

UNDER the above heading we notice, in the New York *Electrical Engineer* of August 20th, a letter from Professor J. A. Fleming, having especial reference to the proposed connection of the names of Franklin and Henry with the titles of certain electrical units. However much these names are deserving of being held up to admiration, and of being preserved to memory, we think that the mania for inventing fresh terms has been carried to an extreme. Is it not sufficient that the names of Ampère, Faraday, Joule, Ohm, Volta, Watt &c., have been tortured, twisted, and scattered recklessly hither and thither? Must we further submit to an amplification of the already overstocked vocabulary of electrical terms? A veritable craze seems to have taken possession of the electrical world, but there is, after all, an amusing phase of the disease. The writer of the letter above alluded to, suggests that “the practical unit of self-induction in the system of measurement which employs the ampère, volt, ohm, &c., should be called a *hen*.” Oh, shades of poultry yards! will not every barn-yard rooster arise and crow out his indignation? The following paragraph—“and bestow upon the unit a name which carries no suggestion of dimen-

sions, and which is susceptible of being used in such compounds as *micro-hen* and *milli-hen* convenient for subdivisions of the unit," seems to us a direct insult levelled at Dame Partlet and her callow brood. The professor goes on to say, "There is nothing to prevent any one speaking of *true hens*, *legal hens*, or *British Association hens*, if it is required to be very precise." What delicate definitions! Should suggestions of the nature proposed by Professor Fleming be generally adopted, an unlimited field is presented to the aspiring nomenclaturist; the possible variations being almost endless, limited only by the number of names borne by men more or less famous in electrical science. But, perhaps, we have taken Professor Fleming's suggestion too seriously.

Electric Light at  
Bath.

ACCORDING to accounts which have reached us at various periods the electric lighting at Bath is no unmixed blessing. After the installation had been running a short time many complaints were made of faulty lamps; now matters seem to be a little worse. On Sunday night we are told the donkey engine used in the central station to feed the boilers broke down, and the alternators were shut off putting out the incandescent lamps, which were not restarted that evening. Shortly after the arc machines, with the exception of one, were stopped for about three hours, putting out half the street arc lamps and leaving the works in darkness, the men having to work with candles and oil lamps; later on, we are informed, the whole of the public arc lamps were discontinued for an hour. We are afraid this is calculated to bring some one into discredit, whoever that someone may be.

Kemmler's Execution.

WHENEVER we take up an American paper, which is published beyond the sphere of influence controlled by the alternating current party, we find such remarks as the following by no means uncommon: "But the horrible part of the execution, so many papers say, was the fact that the flesh on the top of the head and at the base of the spine was burned, and that death by electricity is therefore a failure." It is very sad indeed to think that a man like Kemmler, who was devoid of all that pertains to humanity, should be slightly burned. This little preface to his hereafter should be considered simply as a preliminary that he might become to some degree accustomed to his future state, and we believe that a continuance of the law which made death by electricity legal will have a salutary effect upon the criminal class in New York State, and that other States might do worse than adopt it.

Elmore's Copper  
Companies.

THE *Financial News* of September 3rd recalls its words of June 11th, to the following effect:—"Next to the rise and fall of the Paris Syndicate, the most important event which has happened in the copper trade of late years is the discovery of the Elmore copper-depositing process," and adds: "When the Société des Métaux fell to pieces, M. Secrétan was under contract to buy the foreign patents for £700,000. Two official statements have just been published respecting the relative estimated value of the shares in the English and Foreign Elmore's Copper Depositing Companies. It is pointed out with regard to the former that the plant now in process of completion will yield a profit of £174,720 per annum, enabling the company to pay a dividend of 100 per cent. and leaving a surplus of

£34,720. It is deduced from this that the shares which now stand at about £7 should be worth £20 each, and Mr. Elmore says that 'at no very distant period they will stand at £50 each.' The shares in the Foreign Company are estimated on the basis of the sale of four groups of patents now in negotiation, the total anticipated receipts from which amount to £566,500, giving £17 each to the priority shares and more than £34 each to the founders' shares, apart from the value of shares in subsidiary companies." The above predictions are very pretty, and doubtless will send a warm thrill of excitement through the holders of Elmore copper shares, but they must, of course, be taken with a grain of salt. We sincerely hope the forecasts will be verified, and that the example of the Société des Métaux may not be followed, for with success no one will be harmed. We should, however, much like to get at genuine manufacturing results rather than the price rigging through means of vague statements of immense profits.

Bleaching by  
Electricity.

THERE was a paragraph in last week's *Engineering* which a practical bleacher informs us could only be made by an enemy to bleaching by electrolysis or a promoter of the Chemical Union. Our correspondent is ready to prove that such results as those reported would be much dearer than bleaching by chloride of lime, and would condemn the electrolytic system if nothing better were done. He encloses us the following letter from the London Electric Bleaching Company to a Manchester firm, and expresses his readiness to conduct the experiments in the presence not only of paper makers but of the representatives of the electrical press:—

*Bleaching by Electricity.*

Dear Sirs,—Referring to our former correspondence, we intend next month to demonstrate on a commercial scale the superiority of our process for bleaching by electricity over the present method by means of bleaching powder. By our process, each manufacturer can produce the quantity of bleach he requires daily, without any more trouble than in preparing the solution of bleaching powder. The plant and machinery are not expensive; and are easily adapted to the present system. The bleach produced by electricity has the same decolorising properties as chloride of lime, and none of its drawbacks. By our electrical process bleachers will be enabled to produce the equivalent of a ton of bleaching powder, at half the present cost. Our demonstrations (which will last a fortnight) will show, 1st. The transformation of common salt and water into bleaching liquor of the required chlorometric strength for the ensuing operations. 2nd. The bleaching of a few cwts., or say half a ton of paper pulp, or of vegetable fibres, in less time, and at half the cost, as compared with when bleaching powder is used. Kindly let us know if you will favour us with your presence, or with that of your representatives, and as soon as our installations are completed, we shall let you know the date of our experiments; and, if you wish it, we will bleach your own materials.

Electric Lighting in  
Birmingham.

IT is probable that big things may be expected in the way of electric lighting at Birmingham very shortly. Already a good many street mains are laid in the central portion of the town, and the work is being rapidly pushed on. The company responsible for this is the Birmingham Electric Supply Company, which had the provisional order transferred to them by Messrs. Chamberlain and Hookham last year. Their order enables them to supply the electric light to the richest neighbourhood, in which are all the public institutions, theatres, banks and offices. It is expected that a station will be erected capable of supplying 20,000 lights. It is high time that the chief town of the Midlands bestirred itself to acquire a good system of electric lighting; private lighting has been carried on, but only in one or two of the theatres and other buildings. It is, therefore, with satisfaction we hear of the work likely to be accomplished by the local company.

## THE HEDGEHOG TRANSFORMER.

LAST year Mr. Swinburne brought forward the theory that an open iron circuit could be made more efficient than any form of closed iron circuit transformer. The loss in a transformer is made up of loss in copper due to resistance and the loss in iron due to hysteresis. In calculating the efficiencies of transformers, the loss in the iron has generally been left completely out of account, and the loss in copper alone considered. Hence the efficiencies of 97 and 98 per cent. claimed for closed iron circuit forms. If the loss by hysteresis is taken into account, allowing the losses as given by Ewing, the loss in iron in closed circuit transformers, as usually designed is some 10 per cent. of the full load. As the loss in iron goes on all the time a transformer is in circuit, this is very serious. The proportion of actual to possible output of energy per day varies in different districts, but in most stations the average use of lamps is less than two hours a day, including all the lamps installed. The transformer must be large enough to feed all the lamps installed, so it runs, say, an average two hours of full load a day. If there is a loss of 10 per cent. of full load in the iron, this gives an actual efficiency of 45 per cent., even neglecting the loss in copper. In the Hedgehog form the proportion of iron is very much reduced. The cross section of the iron is much less, and the length is about one-third of the closed circuit form, as it has not to surround the wire. The result is that, even in small transformers, the iron loss is under 1 per cent. of the full load. One per cent. of the full load gives 89 per cent. all day, neglecting copper loss, against the 45 per cent. of the closed circuit. This is neglecting copper, however, and the copper loss is greater in the Hedgehog form, so this is an exaggerated comparison. Such a transformer really has an efficiency of about 87 per cent. all day.

The theory of the Hedgehog form is this: If a closed iron circuit is used, the iron circuit must be long, to embrace the copper coils. The only way to shorten it is to make the copper coils smaller. This means using a higher current density which, is wasteful, or fewer turns of copper. Fewer turns of copper demands either

Similarly, in a composite magnetic circuit of iron and air, the magnetic resistance is low if there is never a high magnetic current density or induction in the air, which has high specific magnetic resistance. The magnetising current in a Hedgehog is high; but as it is a quarter of a period behind the primary current in phase, and as the primary wire has to be large enough to carry the primary current, the loss in watts is small. As this loss goes on all day, however, it is by no means unimportant, and has to be included in getting out the efficiencies of these transformers. The construction of these transformers, as carried out by Messrs. Swinburne and Co., of Teddington, is very simple. A gun metal casting of cross shaped section forms the backbone. It is spread out at each end, forming legs at one, and taking the circular terminal board at the other. It also carries insulating flanges which form the ends of the coils. Into the four recesses in the core are put four bundles of soft iron wire. These are taped over, and the secondary is wound on. The secondary is then covered with two layers of ebonite, and the flanges are also faced with the same material. The primary is then wound on in two compartments, separated with ebonite after the manner invented by Gramme, so that both ends come outside, and as far removed from each other as possible. The ends of the core are then spread out, and the transformer tested under 4,000 or 5,000 volts; the insulation in megohms being read by a peculiar instrument which measures the effective resistance under an alternating current. As iron cases cannot be used, as they would be magnetised by the transformer, and as any metal would have Foucault currents generated in it, stoneware jars are used for cases. These have lids bolted down with holes for the leads, as shown.

ELECTRIC LIGHTING MANY TIMES  
SUPERIOR TO GAS.\*

By PAUL HOHO.

At a conference which took place in connection with the last general assembly of the Union of Engineers graduated at the University of Louvain. I had occasion to make a comparison between certain figures relative to the yields of an electric incandescent lamp and a jet of gas. I was greatly surprised at the astonishment which my conclusions evoked, even amongst electricians; and I was induced thereby to repeat my calculations in our society with a view to raising a discussion so as to accentuate the affirmative character of the conclusions which might result. In any case it is well to proclaim aloud and to reiterate figures which ought certainly to find a place on the leading page of every engineer's pocket book. The matter is one of extreme simplicity and, frankly, I ought to apologise to you for introducing one so elementary.

The entire question reduces itself to this: What amount of energy is required by an incandescent lamp on the one hand and a gas jet on the other, in order to produce an equal amount of light, for example, an amount equivalent to 16 candles?

Allow me to make a slight digression for the purpose of assisting somewhat in preparing gas for the sentence which is about to be pronounced upon it by figures which admit of no appeal.

The action of the incandescent lamp is based upon the fact that the energy of the electric current in traversing its filament is transformed by reason of the resistance offered by the latter, into calorific energy, which emanates from the filament in the form of calorific rays. But, as you are aware, a solid body if placed in a certain temperature becomes incandescent, that is, a part of the calorific rays becomes luminous.

\* A paper read before the Société Belge d'Electriciens.

a higher induction in the iron, or a greater cross section, and both of these mean greater loss by hysteresis. If the iron circuit is opened, the sides of the embracing core can be removed, so the loss by hysteresis is divided by three. As there is now plenty of room for copper, the turns and cross section can be increased, and the iron reduced still further. The object of introducing the closed iron circuit was to reduce the magnetic resistance. An open circuit transformer has much higher magnetic resistance. The question of magnetic resistance is not so important as might at first sight appear. Its increase demands more excitation, or more magnetomotive force, and this increases the loss in copper. The best form is thus a compromise. The Hedgehog ends are to reduce the magnetic resistance. In a conductive circuit the resistance is low, if the current density is low in all parts where the specific resistance is high.

For the complete utilisation of this property it would be necessary to attain to such a temperature that the proportion of the luminous rays to the total radiation is the maximum. Unfortunately the physical constitution of the filament, as we actually possess it, does not admit of its being placed above a certain temperature, and we are compelled, therefore, to moderate the action of the electricity in the lamps. The incandescent lamp, as far as it goes, is consequently very far from realising our ideal, and in order to bring about its perfect action upon this principle, electricity is compelled to await the progress of chemistry, which I hope will one day give us a body upon which electricity will be able to exercise its action without restraint. I will not expatiate upon what may be reasonably expected by electricity upon this head, but will base my calculations upon results as they have been actually obtained.

As regards the gas jet, I would first of all remark what a singular idea was that which sought to light up the universe by means of a flame. A flame, as you are aware, is essentially composed of gaseous elements, in which is found a comparatively slender quantity of solid particles. Now, we learn by physical science, that from gas, at whatever temperature it may be carried, emanates very little or no light; all its rays are calorific, and the light which emanates from the flame, is exclusively composed of solid particles, notably carbon.

Is it possible to imagine a more irrational method of lighting? You may attempt to excuse it by saying that it has for a long time been the only one we knew. I admit the excuse, and even that it is a serious one, but you must also confess that it is the only one.

*A priori*, we are in a position to foresee the wretched result to be had from a gas jet; and it only remains to compare the figures.

An incandescent lamp of 16 candle-power consumes at its terminals 2, 2½, 2¾, 3 to 3½ watts per candle, or, 32, 36, 40, 48 to 56 watts for every 16 candles, which amounts to 3·2, 3·6, 4, 4·8, 5·6 kilogrammetres per second for every 16 candles.

On the other hand, a 16 candle-power gas jet consumes 180 litres and more per hour.

Now, a cubic metre of gas, by its combustion, gives out 6,000 calories (according to M. Fresca's calculation); and 180 litres will give out  $6,000 \times \frac{180}{1,000} = 1,080$  calories;  $1,080 \text{ calories} = 1,080 \times 424 = 457,920$  kilogrammetres, which a gas jet consumes per hour, that is  $\frac{457,920}{3,600} = 127\cdot20$  kilogrammetres per second.

It only remains now to compare this consumption of energy with that of an incandescent lamp as set out below.

$$\frac{127\cdot20 \text{ kilogrammetres}}{3\cdot2} = 39\cdot75;$$

$$\frac{127\cdot20 \text{ kilogrammetres}}{3\cdot6} = 35\cdot28;$$

$$\frac{127\cdot20 \text{ kilogrammetres}}{4} = 26\cdot50;$$

$$\frac{127\cdot20 \text{ kilogrammetres}}{5\cdot6} = 22\cdot70;$$

From these I conclude that in order to produce a luminous intensity of 16 candles, a gas jet consumes 22·71 to 39·75 times more energy than an incandescent electric lamp, counting the latter at 2 to 3½ watts per candle, and the consumption of gas at 180 litres per hour. I conclude, further, that the incandescent supplies an illumination absolutely 22 to 40 times that of a gas jet.

That is all I had to prove, and I could content myself with pointing out that in order to destroy these conclusions it will be necessary to invalidate the preceding figures, which is, I repeat, impossible. However, as I foresee myself being answered in the eternal refrain of "theory and practice," I will dwell a little longer upon the matter than it really demands.

In the above conclusion I have specified all that the

figures teach; they tell us nothing more, but, above all, nothing less. We therefore have it that the incandescent lamp constitutes a transformer for the production of luminous energy 22 to 40 times more perfect than the gas jet, comparing the two individually without regard to the production of energy by the one, or of gas by the other. This is the first thing to be established.

Next, as regards the production of electric energy and the production of gas.

Energy is present in nature under various forms; under that of chemical energy in carbon and other bodies—as calorific energy, as the energy of gravitation and of masses in movement, for example, the fall and flow of water.

Gas can only be obtained from coal, and, in certain cases, where it already existant in nature, whilst it cannot be drawn from energy which exists in other forms unless in the most roundabout and impossible way.

Electric energy, on the contrary, may be obtained by the transformation of energy existing in any form, with various results. Thus coal may be transformed into electric energy by a series of transformations yielding a feeble result which is successively diminished by each transformation; the mechanical energy which may be employed upon a shaft moved by a fall of water, may be transformed into electric energy and afford results unknown in any other industry, 85, 90, and even 93 per cent., for instance.

Therefore in comparing electricity with gas, it would be absolutely unreasonable to deal with energy as existing under one form only.

If gas, for the sake of a cause which is otherwise indefensible, demands that the comparison be made from the standpoint of the energy of coal compared with that of gas, electricity will not shrink from the comparison; but should electricity in its turn call for a comparison with other forms of energy, the protests of the advocates of gas would only be equalled by the disastrous results to their client.

However, for the production of light, it suffices on principle to have a suitable transformation of energy, nothing but energy, and this as much as possible free from carbon fumes and from the emanations of carbonic acid and other similar products whose influence is little beneficial. It is true that coal is to be found in large quantity in nature, and that in this country, as a rule, it offers the most economical and convenient form of energy for our needs. But we are not merely arguing the case of Brussels, and without admitting the hypothesis that some day or other we shall have to make use of the Niagara Falls, we have still in this country waterfalls and flows which could be easily utilised, and which have, in fact, been so very frequently.

We by no means decline to institute a comparison with gas on the standpoint of coal or of gas even, but first let us point out the insufficiency and exclusiveness of the comparison.

Thus, 10 kilos. of coal furnish a maximum of 3,000 litres of gas, or a quantity sufficient to feed ten jets of 16 candle-power during one hour and forty minutes. To produce electric energy from coal, we are obliged in the first place to transform, by a series of transformations, the energy of coal into mechanical energy and next into electric energy. With the aid of a good condensing engine, 10 kilos. of coal will furnish 8 horse-power hours upon the shaft, by means of which the dynamo electric machine will furnish 8 H.P.H.  $\times 75 \text{ kg.} \times 9\cdot8 \text{ w.} \times 80 \text{ per cent.} = 4,800 \text{ watt-hours}$ , or the amount of energy necessary for supplying 10 incandescent 16 candle lamps during 8¼ths to 15 hours.

Result in favour of electricity:

$$\frac{8\frac{1}{4} \text{ to } 15}{1\frac{2}{3}} = \frac{5\frac{1}{2} \text{ to } 9}{1}$$

and, moreover, the first transformations of the energy, up to the driving shaft, before electricity had come into play, had only furnished a total rendering of 10 per cent.

In fact, 1 kilo. of coal gives an immediate yield of

5,000 calories = 2,120,000 kilogrammetres, whereas upon the driving shaft we have 0.8 H.P.H.  $\times$  75 kg.  $\times$  3,600 s = 216,000 kilogrammetres, which gives a rendering of  $\frac{216,000}{2,120,000} = 0.10 = 10$  per cent.

Let us now make the comparison on the score of gas, that is, by employing the 3,000 litres of gas produced by 10 kilos of coal on the one hand directly in the gas jets, and on the other for producing, by means of various transformations, electrical energy for the supply of incandescent lamps. The 3,000 litres of gas will supply, it is said, 10 jets of 16 candle-power during one hour and 40 minutes. On the other hand they will supply upon the driving shaft of a gas motor  $\frac{3,000}{700} =$

4.286 horse-power hours, by means of which the dynamo will furnish 4.286 H.P.H.  $\times$  75 kg.  $\times$  9.8 w.  $\times$  80 per cent. = 2,560 watts hours, or the amount of energy required for supplying 10 16-candle incandescent lamps during  $\frac{4}{7}$  to 8 hours.

Result in favour of electricity

$$\frac{4\frac{2}{7} \text{ to } 8}{1\frac{2}{3}} = \frac{2.74 \text{ to } 4.8}{1}$$

And, moreover, the gas motor, which consumes 700 litres of gas per horse-hour only returns 15 per cent. yield. In fact 700 litres of gas give immediately

$\frac{700}{1,000} \times 6,000 = 4,200$  calories =  $4,200 \times 424 = 1,780,800$  kilogrammetres; whilst on the driving shaft they gave 75 kg.  $\times$  3,600 = 270,000 kilogrammetres, or  $\frac{270,000}{1,780,000} = 0.15 = 15$  per cent.

These figures point their own conclusions sufficiently clearly, precisely, explicitly and instructively to be developed by us.

I have only to point out what follows as a consequence:

1. The loss which occurs in obtaining electric lighting by means of coal or gas, is not to be attributed to electricity but to the successive transformations of energy with very slender results, before electric energy is obtained.

2. Directly electricity comes into play, that is when mechanical becomes transformed into electrical energy, the yield is enhanced to 80 per cent. (as mentioned in my calculation), and may in fact reach to 85, 90 and 93 per cent. and more.

3. Therefore in spite of the preliminary very unfavourable transformations electricity, a total result is obtained which is notably superior to gas, as I have shown in the foregoing figures.

These will be found to gain in importance and to accentuate the advantages of electricity if we take into consideration the following three facts:

1. The transformation of energy in general in all these forms makes continuous advances. Whilst these advances constitute an immediate advance for electric lighting, they bring with them no advantage for gas lighting. It is true that gas is in no way prejudiced by the transformations undergone by it before its utilisation, but its failure consists entirely in its employment as a lighting medium.

2. The transformation of electric energy is making rapid progress. The same cannot confidently be said of gas, which after over a hundred years of use, finds itself already outstripped by a luminant which hardly counts an existence of 10 years.

3. Electric energy is peculiarly transportable from long distances, a fact which enables it, and will enable it, to overcome local circumstances disadvantageous to its production, by enabling its production in localities where the conditions are more favourable.

## PROGRESS OF TELEGRAPHY IN AUSTRIA.

[FROM A CORRESPONDENT.]

RECENTLY an improvement in the Morse apparatus has been effected by means of an invention made by Joseph Stulc, of Jägerndorf, the manager of the Moravia-Silesia central line. This invention is not an improvement or a simplification of the Morse apparatus itself, but it promises noteworthy results as regards economy of working material. The idea upon which Stulc has effected his arrangement of stations is founded upon the division of the current and upon its insulation. He has arrived at the important result that local batteries can be definitely dispensed with in telegraph working. This is an important advantage in the large telegraph systems of the Government, and in railway lines with many branches, as it involves a great economy of material, and dispenses with the trouble of filling up the batteries and exchanging those which have become unserviceable.

With this invention, which has been arrived at in a very simple and ingenious manner, involving no extra outlay, there are connected other advantages of much importance, especially on railways which have to maintain separate batteries to work signals (bell signals and distance-signals). Thanks to the idea of Stulc, which has been tested experimentally, an economy in working material of nearly 50 per cent. has been attained with a current which does not exceed the normal strength.

Of not less importance is the advantage of the same idea in subdividing the current, as Stulc has succeeded in working with a different strength of current. It often happens that the line current, from different causes, is weakened to such an extent that the Morse apparatus gives only illegible signs, whether because the two stations corresponding with each other are too far apart or that various intervening stations disconnect their arrangements on the approach of a thunderstorm. Stulc has met this difficulty in a most satisfactory manner.

It must further be noticed that Stulc has devised a certain method of protecting the telegraphic stations from lightning.

Another not less surprising success of the same inventor is that he has rendered it practicable not only for stations of the same portion,  $\alpha$ , of the main line, A, to correspond with the stations of the branch line, B—which is nothing new—but also the stations of the portion,  $\beta$ , of the main line, A, may speak with the same branch line, B, a result which has hitherto been impracticable. This is important, for, in the first place, the communication of messages through intermediate stations is a waste of time; and, in the second, it increases the chances of error. Finally, it must be mentioned that Stulc has encountered a misfortune at the very outset. In his delight at the success he opened heart and mouth to a specialist. The latter, abusing his confidence, applied for patents in Austria and Germany. This affair has occasioned an investigation which may possibly have to be decided by the courts of law. Fortunately the "good friend" has not fully grasped the idea of Stulc, so that there are many important defects in the scheme of the patentee. Herr Stulc has received many offers of financial assistance from patent offices abroad.

## WHAT CONSTITUTES A DANGEROUS ELECTRICAL CURRENT?\*

By NELSON W. PERRY, E.M.

PART II.—CONCLUDED.

THE average normal resistance of an adult body from hand to hand may be accepted as 1,000 ohms. As the highest estimates have usually placed the quantity ne-

**Copper in America.**—A representative of one of the largest copper houses in America says the demand for copper wire is beyond the wildest hopes of the manufacturer.

\* *Western Electrician*.

cessary to kill at not more than one ampère, if passed from hand to hand or head to foot, the electromotive force that must be associated with the same idea will be 1,000 volts, because the pressure is capable of forcing just one ampère of current through a resistance of 1,000 ohms. We must not, however, assume from this that all currents of 1,000 volts that pass thus through the body are necessarily fatal, because currents may exist of vastly greater electromotive force but lacking in quantity—such as, for instance, the spark from a Leyden jar, which may be many thousand volts, and yet be so insignificant in quantity as to permit of its being taken without unpleasant effects. Then, again, if we should assume a case in which, say, a single ampère of current would only be just sufficient to cause death, it is not to be taken for granted that death could not be caused in any way by *less* than one ampère.

Prof. Tait and Balfour Stewart, in their joint work, "The Unseen Universe," call attention to the different effects that may be produced by the same amount of energy when applied in different ways, and cite as an illustration, that a pillow weighing 30 lbs., moving at a rate of 10 feet per second, that is a velocity it would attain if it had fallen a little less than 2 feet, has nearly the same energy as a pellet of No. 1 shot as it leaves the muzzle of a fowling piece. "How different the quality of these equal quantities of energy of the same kind," say they.

Then, again, it is observed that a force suddenly applied will often produce very different results from an equal one that has been gradually applied, and an interrupted or alternating current of electricity is found to produce more violent physiological effects than a continuous or steady current of the same electromotive force.

In the present state of our knowledge, it is not possible to arrive at the increased effect quantitatively, but that there is increased effect is a matter of very common experience. Mr. Edison is quoted as having stated that three volts of the alternating current would be fully equivalent, in physiological effects, to eight volts of the direct current. Mr. Westinghouse would probably not admit that there was anywhere nearly so much difference between the two.

It is desirable that we do not here confuse the effects due to the breaking of a circuit.

Everyone is familiar with the thumping that occurs when the water is suddenly turned off in a long pipe. There is no jar when the water is turned on at the faucet, but if the pipe is very long, and the water is under considerable "head," a sudden turning off of the flow may result in such a thump as to burst a pipe capable of withstanding a very much greater pressure than that due to the head of water. In fact, this extra pressure, due to the sudden stoppage of a flow of water, is utilised in the hydraulic ram to force water higher than its source.

Now, in the flow of electricity, we have an exactly similar phenomenon. While the sudden closing or starting of an electric current will produce momentary physiological or magnetic effects in excess of the same current more gradually applied, its electromotive force is not increased by its sudden starting; but if a circuit be suddenly broken, we have effects exactly analogous to those observed in the case of water in a pipe. If the wire be very long, these increased effects become more apparent, and, if the long wire constituting the circuit is coiled many times around a soft iron core, as in the case of an electro-magnet, the voltage may be enormously increased by the breaking of the circuit. This effect, which is said to be due to momentum in the case of water, is called the "extra current," and is ascribed to "self-induction" in the case of the electric current.

In some cases this extra current may be several times as strong as the normal current, and it thus becomes apparent how an otherwise harmless current may become an agent of death.

For instance, where a man might catch hold of a broken trolley wire carrying a current of 500 volts with safety, if it were merely hanging down and not touch-

ing the ground, he would in all probability be instantly killed if he found such a trolley wire lying on the ground and he should pick it up, because in the first case he would be merely completing the circuit through his body to the ground of a current that is usually considered safe, and in the other, by breaking such a circuit already completed, he would get the benefit of the "extra current" which might be several thousand volts.

It may be laid down as a very safe rule to follow, therefore, to be always suspicious of every wire one meets with in these days, but be especially suspicious of every wire one finds lying on the ground. It is harmless there, but it may be exceedingly dangerous to lift it up. If it is a charged wire, and one can never be sure that it is not, it is sure to be more dangerous to handle than its normal current would imply.

While a dose of electricity not sufficient to kill is exceedingly painful, as the writer and almost every other electrician knows by experience, it is perfectly certain that a sufficient dose is perfectly painless.

Jules Verne, in his story, "A Journey to the Moon," places his heroes in an immense projectile, which is fired at the moon from a cannon of suitable proportions. After the projectile has started on its journey, the hero is at first mystified by the fact that he has heard no report of the explosion. He refers to his figures, and finds that, according to his calculations, the projectile should have an initial velocity greater than that of sound. He concludes, therefore, that he could not have heard the explosion because he has kept ahead of the sound.

A little over a year ago the writer, by invitation, formed one of a select audience of gentlemen before whom Prof. Maybridge showed with the lantern a series of instantaneous photographs. In order to make the intervals between the exposures as well as the times of exposures exceedingly short, the plates had been exposed and stopped by means of an electric current.

One very interesting series of pictures that he showed was intended to illustrate the slowness of the brain in receiving impressions. To illustrate this, he had employed two women—one stood in a bath tub and the other stood upon a chair and poured a bucket of water over the former's head and shoulders. In order to make the shock more intense, Prof. Maybridge had had the bucket filled with icewater, unknown to the victim, who would scarcely have consented to the ducking had she known the temperature of the water. One view represented the water tipped over, and the water falling, but not yet quite touching, the girl's head. The next view showed the water already splashing from her head and shoulders, but although the water had already touched her, and some of it had splashed off from her shoulders, still she had not yet received the sensation.

The third picture showed her just beginning to respond to the shock, and the subsequent ones illustrated the various phases of this response; but what interests us here in this connection is the second view. The electric current had in that case first exposed the plate, and then after a very short interval had shut it off again; that is to say, had acted twice with an interval of time between the two sufficiently long for the sensitive plate to take an impression of the view, and this after the icewater had touched the woman's shoulders, and *before* she was conscious of it.

This is the reason that death by electricity if applied in sufficient doses must be absolutely painless, that with the velocity of light, or at about 186,000 miles per second, the impulse has gone on its way and completed its work. In fact, there are reasons for believing that death by this means is so swift that the dose could be repeated a number of times within the interval that is known to elapse between the receipt of an injury and the cognizance of it by the brain.

In receiving an electric shock it makes a very great difference how we have come in contact with the current, and in accidental cases it is almost impossible to tell just what the conditions were, and consequently how

much current passed through the body. For instance, let us take an ordinary arc light circuit such as are common in all of our cities. Such a circuit carries a current usually of 9.6 amperes at a pressure of 45 volts. I speak of this kind of circuit because in the popular mind it is considered particularly deadly. One may catch hold of the bare conductor with both hands without feeling the slightest shock, because then the body forms what is called a "derived circuit" of high resistance, while the wire between the hands is of very low resistance. The law of flow in such cases is that the current will divide itself among all paths to which it has access in proportion to the conductivity of those paths. In the case just cited the conductivity of the wire between the hands may be 5,000 times as great as that of the body, and in that case 5,000 times as much current would take that path as the other, leaving  $\frac{9.6}{5000}$ ths ampere the quantity that would pass through the body—a quantity so small as not to be perceptible.

If one placed his hands on the wire so that a lamp came in between them, the resistance of the lamp would be added to that of the metallic path, and its conductivity would no longer be 5,000 times as great as that of the body—it would be less, and therefore a greater proportion of the current would pass through the body than in the first case. The greater the number of lamps "short-circuited," as the technical phrase is, the smaller the proportion of the current that will follow the wire, until if so many lamps and other resistances are included between the two hands that the resistance of that part of the current is as great as that of the body, then half the current will pass through the body, and half will follow the wire.

It might be perfectly safe, therefore, to catch hold of both of the wires of the so-called deadly arc light circuit if one were sufficiently far from the dynamo so that there were but two or three lights beyond him, whereas it would be surely fatal to do the same thing near the dynamo, where, by so doing, one would short-circuit many or all of the lamps on the circuit as well as the resistance of the circuit itself.

In practice, however, it is never safe to touch even one of the bare wires of such a circuit unless perfectly insulated from the ground, for the reason that there are liable to be leaks or ground connections somewhere along the line, and by touching one wire, while standing upon the ground, a path would be opened for the current from the point touched through the body and the earth to the leak, thus short-circuiting all of the resistances between the two points.

It is therefore another safe rule to follow—never connect two points of an electric circuit between which there exists a high resistance of any kind, by means of the body, as the high resistance forms an obstacle to the passage of the current through that conductor, and forces it to take any other paths open to it.

In the case of a shock by coming into contact with an arc light wire, while in more or less perfect electrical connection with the earth, it is always due to an earth connection somewhere else on the line. It is not infrequently claimed in such cases that the shock received is due to the full force of the current, which in many arc light circuits runs up to 3,000 volts or over. This, of course, is seldom true. In fact, in such cases it is usually utterly impossible to tell just what current was received; first, because the exact location of the leak or leaks on the line is usually never known at the time of the accident, and therefore it is impossible to tell just how many lamps or other resistances have been short-circuited; and then, in the second place, the normal resistance of the body is usually not the only one concerned in the short-circuit—there is the undetermined resistance of the boots, and also of the ladder, or whatever else one is standing on, and also the resistance due to imperfect contact with the wire as well as that of the leak itself. Since the quantity of current that will pass through the body is dependent upon all of these factors which are usually undeterminate, any statement as to what current a man received under such circumstances is at best the merest guess, and usually the poorest kind of a guess at that. We now

see, however, how one man may be killed and another be only slightly injured from contact with the same circuit.

The case would be somewhat different, however, if, having hold of the conductor with two hands, it should become broken between the points at which it was grasped. The body would then be virtually short-circuiting an infinite resistance, and would receive the full current of the machine up to the capacity of the machine to force it through his resistance. That portion of the circuit nearest the dynamo would be more dangerous to try the experiment on than that portion furthest removed—in fact, there would be no difference where it was tried; it could have but one result in the case of machines of large capacity, viz., death. The various high resistances which different investigators have attributed to the human body, aside from the other modifying causes that I have shown, make it apparent how possible it is, under circumstances otherwise apparently favourable, for a person to receive a very slight shock comparatively from a very strong current.

On the other hand, several electricians have testified that they have taken currents of very high electromotive force—one in particular testifies to having taken 10,000 volts, and the fact that he lived to tell it is evidence enough that it was not fatal. I have no reason whatever to doubt that it was so, and if there were any object in doing it, or rather if there were sufficient object, I would not hesitate to take myself an alternating current of the same or even greater voltage. I should want to take it in my own way, however, and I could do it without fear of fatal effects, whereas I should feel sure of being instantly killed if I took one ampere of current at 1,000 volts from hand to hand, or from head to foot in the most approved way.

Another feature that has undoubtedly been a very potent factor in the discussion of this question of the uncertainty of the physiological results from the electric current should be referred to. In 1888, the State of New York enacted a statute substituting death by electricity for death by hanging. Any change so radical as this would naturally have attracted wide attention and given rise to considerable discussion, and indeed, with the information then at hand as to the behaviour of the human body towards electricity, there seemed ample grounds for a difference of opinion not only as to the advisability of the change, but also as to the practicability and certainty of the new method. Of course, none of the manufacturers was willing to have his machine used for this purpose. The electrical journals of the day teemed with contributed and editorial comments favouring the views of the manufacturers, and the validity of the law authorising the execution of criminals by electricity was severely attacked, and not allowed to rest until affirmed by the highest court. The electrician, through whose instrumentality the machines were procured, and other arrangements for the carrying out of the law were made, was professionally ostracised and branded with most opprobrious epithets, and every endeavour made to manufacture a public opinion against which it would be impossible for such a law to stand.

The company, whose machines were procured, is the one that has been most active in the introduction of what are known as high potential alternating currents. Their business rivals, who confine themselves to the use of the direct current usually at lower potentials, were not slow to take advantage of what appeared to them a business opportunity, and we therefore have seen arrayed against each other the representatives of the two systems—the high potential, and especially the alternating current representatives—trying to defeat the execution of the law, and using every argument that presented itself to prove the extreme variability of the resistance of the human body, and therefore the uncertainty in any given case as to the probable action of a given electromotive force, and the low potential men endeavouring to prove the necessarily dangerous character of all high potential currents in general, and of alternating currents in particular.

Thus we have had the leading representatives of the two systems appearing in print in one of our leading periodicals, each showing the harmlessness of his own system, and the dangers of the other, and each suggesting a series of precautions, which, if observed, would reduce the danger from electrical currents to a minimum, in a way perfectly satisfactory, doubtless, to himself, but not to the other, because in each case the following of the suggestions of each necessarily involved the abandonment of his opponent's system.

Since perhaps the majority of electricians actively engaged in this country are identified with either one or the other of these two great interests, we find them, too, taking sides—usually with the interest with which they are connected. The old saying that “the wish is often father to the thought” is not merely a pleasant jingle of words, but a psychological fact, and we thus have had most sincere arguments on both sides of the question by men who intended to be and were thoroughly honest.

As a person who is identified with neither party, and yet who has business affiliations with both, I have thought that I could discuss the question free from the bias that has naturally existed in many other instances, and my conclusions from the facts and evidence at hand are, that a large majority of those who are free to weigh the evidence dispassionately are in no uncertain mind that a single ampère of current passing through the body from hand to hand or from head to foot is as surely fatal as anything we know.

I also believe with a great many who have given this subject much thought that a very much less quantity than one ampère would be sufficient to insure immediate death. I have little sympathy, however, with the attempt that has been made to distort the facts in the case to the injury of the business of one of our largest electrical interests, or with that other attempt to create a false sentiment against the so-called “debasement of science,” which it is claimed is involved in the substitution of the electric current for the guillotine or the halter.

### COMPARATIVE TESTS OF LEATHER AND CANVAS-RUBBER BELTS.\*

By SAMUEL WEBBER, C.E.

THE question of belting for driving the high speed dynamos in electric light and power stations, is one of considerable importance, and one on which I am often called to express an opinion.

In the first place, let me lay down as a general law, too often neglected, that the value and driving power of a belt depends upon its complete flexibility, and also on its evenness and softness of surface; which two qualities combined, permit perfect contact with, and close adhesion to, the surface of the pulleys. The next point is the weight of the belt itself, which should be as light as possible, consistent with the extreme power to be transmitted by it. This not only saves waste of power in keeping the belt itself in motion, but reduces the centrifugal action that tends to keep the belt from coming in proper contact with a small pulley at high speed. This matter, though important, is often overstated, much of the trouble often noticed being due to the rigidity and inflexibility of the belt, particularly if a double one, rather than to its centrifugal action. If anyone has ever noticed the action of one of the great cotton mill belts, at Lowell or Fall River, running at a speed of a mile a minute, on a pulley 5, 6, or 7 feet in diameter, he will remember that he has never seen much centrifugal action keeping the belt away from the pulley; but if he has seen a double belt, even at 3,000 feet per minute, run on a 12 inch pulley, he will have noticed a perceptible loss of contact.

For these reasons I would always discourage the use of a double belt, when a single one will answer the purpose on any reasonable width of pulley, or, in any

case, when the pulley is less than 12 inches diameter. Belts can be run as fast as 6,000 feet per minute with perfect safety, and if flexible, will cling to the pulley, and lose nothing by centrifugal action. The consideration of weight leads me to disapprove of the so-called “link belts.” Even with the latest, and I believe the best of these belts, the “Acme” belt of the Page Belting Company, of Concord, N.H., the weight of the belt is given me as 4 lbs. 4 ozs. per square foot, of which 3 lbs. 3 ozs. is leather, and 1 lb. 1 oz. iron.

Now, a first-class single leather belt,  $\frac{1}{8}$ th inch thick, weighs just about 1 lb. per square foot, and I believe that an equal weight of leather, in its normal and natural condition, will transmit more power, with less loss, than if chopped up into scraps and bolted together again, in any way whatsoever.

The cost of leather has led to very many experiments to provide an economical substitute, and the first one of these to notice is the “rubber belt,” or, in other words, a belt composed of several folds of canvas, covered and cemented together with a solution of India-rubber. For work in dye-houses and bleacheries this has proved very valuable; but it is soon destroyed by heat and dust, and I am not aware that it has been successfully used as yet for electrical purposes; in fact, with one exception, the cotton-leather belt, of which I shall speak later, I do not yet know of anything to contradict the old saw, “There's nothing like leather.”

I give herewith the results of a series of experiments made by me at the factory of the Underwood Belting Company, Tolland, Conn., to test the comparative driving capacity of various entirely new belts.

The first test I will note was of an entirely new Hoyt belt, one of the best known on the market. This had been in stock some time, but was tested as it was for the sake of information.

This belt was 12 inches wide,  $\frac{1}{4}$ -inch thick, 31 feet long, and weighed  $34\frac{1}{4}$  pounds. With a tension of  $43\frac{1}{2}$  lbs. it drove 7 H.P. (at 754 feet per minute) and then slipped off from stiffness and lack of sufficient tension. The strain was then increased to  $62\frac{1}{2}$  lbs. per foot, and the belt shortened, in doing so,  $4\frac{1}{2}$  inches. It now carried 7.77 H.P. at 697 feet per minute, and with a load of 11.64 H.P. slipped  $10\frac{1}{2}$  per cent., and slipped off when the load was increased.

The strain was then increased to  $83\frac{1}{3}$ rd lbs. per inch, which shortened it  $2\frac{1}{2}$  inches more, and it now carried 8.88 H.P. at 697 feet per minute without slip. As more load was added it began to slip, increasing until with a load of 14.77 H.P. at 660 feet per minute it slipped 13 per cent., and with increased load slipped off. The belt was then reversed, bringing the softer flesh side to the pulley, the hair side having been previously used. It now carried 16.85 H.P. at 662 feet per minute, and then “jumped the pulley” suddenly with increased load, without having shown any perceptible slip previously. This test showed that on the polished iron pulley the soft flesh side held better than the harder grain.

A pair of Dodge's wooden pulleys were now put on, and the belt replaced, with the hair side to the pulley. We now got 15.29 H.P. without slip, at 739 feet per minute, but additional load caused a slip which increased with the load, so that little more power was shown, and the test was stopped at 15.80 H.P. with the belt still on the pulleys, showing a horse-power for each inch of width at 562 feet per minute.

The next test was to cut the belt down to  $8\frac{1}{2}$  inches wide, which gave an apparent strain of 117.6 lbs. per inch, as it was simply relaced in the old holes. This, on the wooden pulleys, gave 10.19 H.P. without slip at 711 feet per minute, and 11.79 H.P. with a slip of 3.77 per cent., at 699 lbs., and then went off with increased load.

A pair of paper pulleys from Westinghouse, Church, Kerr & Co., were then substituted and the belt replaced as in the last trial. It now gave on these pulleys 15.69 H.P. without slip, at 704 feet per minute, or at the rate of 1 H.P. per inch, for 374 feet velocity. This finished the trials of this belt, which came out as good as new, and had not stretched an inch when we got through with it.

\* Electrical World.

We will now compare this with a series of tests of a very soft and flexible belt, known as the "Schultz Rawhide Belt," under the same conditions.

This belt, 31 feet long, 12 inches wide, and  $\frac{3}{16}$ th inch thick, weighed 29 lbs.

It was first tried, as before, with a strain of 43 lbs. per inch on iron pulleys, grain side to the pulley. This likewise proved to be an insufficient strain, and after giving 6 H.P. without slip, and 9.48 H.P. with a slip of 8.43 per cent., at 725 feet per minute, it went off the pulley with increased load. With the increase of strain to 62½ lbs. per inch it gave 11.10 H.P. at 697 feet per minute, and 16.27 H.P. with 5.66 per cent. slip at 675 feet per minute, slipping off with increased load.

With a strain of 83½rd lbs. per inch we got 15.79 without slip at 667 feet per minute, and 19 H.P. with 5.66 per cent. slip at same speed, going off with increased load. This showed 421 feet per minute per horse-power per inch.

We then put on the wooden pulleys, relacing the belt in the old holes, and got 19.80 H.P. without slip at 691 feet per minute, and 26.16 H.P. with a slip of 3 per cent. at 705 feet per minute. With an additional load we got 26.87 at 693 feet per minute with a slip of 4.59 per cent., and with more load "stalled the engine."

This last test showed 309 feet per minute per horse power for each inch of width, and fairly illustrates the difference between a stiff and a flexible belt.

We, however, split this belt down as we had the other one to 8½ inches wide and repeated on the wooden pulleys. Lacing in the old holes, we now got the strain of 117.6 lbs. per inch, which proved too much for the belt, for although we now got 22 H.P., at 691 feet per minute, *without slip*, or at a speed of 261 feet per minute for each inch of width, the belt "jumped the pulleys" with the next increase of load, and when we tried it on the paper pulleys we only got 16.46 H.P. without slip, at 739 feet per minute. The belt slipped off with the next increased load, and on applying the scales we found that the tension had fallen to 77.7 lbs. per inch, and on taking it off we found it permanently stretched 1¼ inches. We were perfectly aware all the time that we were overloading the belt, but our object was to find how much it would stand.

These experiments confirm the already well established fact that a leather belt will safely bear a strain of 350 lbs. per square inch of area, or 87½ lbs. per inch of width for a belt ¼th inch thick, or 66 lbs. for one of  $\frac{1}{16}$ th inch, or an ordinary single belt, and that the latter in good condition, soft and flexible, will easily convey 1 horse-power for each inch of width at 600 feet per minute. They also show very plainly the difference in the hold on the pulley of rigid and flexible belts, and this difference would increase with the velocity on small pulleys, as both the centrifugal force and the entrainment of air would be greater. An ingenious perforated belt for high speed has been introduced lately by Messrs. Chas. A. Schieren & Co., of New York, which I have not seen in operation, but of which the samples impress me favourably. The slight longitudinal perforations are not sufficient to materially weaken the belt, while at the same time they afford an easy passage for entrained air.

I may be thought severe on "link-belts," but my opposition to them is based on sound mechanical principles, for high speed, and if a great power at low speed is required. When shafts and gears are impracticable I should use a metallic link or chain on "sprocket pulleys," rather than trust to friction. With these remarks I will leave the subject of "leather," and turn to my notes on canvas belts of different kinds. The series of experiments to which I have referred shows a test of a simple canvas or duck belt without any preparation. This belt, 31 feet long, 12 inches wide,  $\frac{3}{16}$ th inch thick, weighed 21½ lbs. It stretched 13¼ inches, with a strain of 43½rd lbs. per inch, gave 4.86 H.P. without slip at 754 feet per minute, slipped 3.83 per cent. with 5 H.P., and slipped off with increased load.

When saturated with size, under a strain of 83½rd lbs. per inch, it carried 5.75 H.P. without slip, at 739 feet per minute, then began to slip as the load was increased, until it went off after giving 10.35 H.P. with 9 per cent. slip.

Next came a "Main" or "Gandy belt," 31 feet long, 12 inches wide, and  $\frac{3}{16}$ th inch thick, weighed 41½ lbs. It was composed of heavy cotton cloth, folded and stitched, and saturated with oil and red paint. It stretched 13¼ inches before lacing with the strain of 43½rd lbs. per inch. It carried 7.20 H.P. without slip at 764 feet per minute; with 8.43 H.P. it slipped 8½ per cent., and went off with increased load. With a strain of 62½ lbs. per inch, it stretched 2 inches more, and drove 8.08 H.P., without slip, at 725 feet per minute, slipped 8.70 per cent. with 9.48 H.P., and then slipped off. With 83½rd lbs. per inch, it stretched 3 inches more, and carried 10.48 H.P. without slip at 732 feet per minute. With 14.22 H.P., it slipped 10 per cent., and then went off.

Next comes a four-ply duck belt, weighing just 1 lb. per foot, and saturated with linseed oil and plumbago. This stretched 7¼ inches with 43½rd lbs. per inch, and drove only 2.40 H.P. without slip, it having been dusted with powdered soapstone, to keep it from sticking together in the fold. The soapstone got rid of, and the strain increased to 62½ lbs. per inch, it carried 13.27 H.P. without slip, and went off with an increase of load. At 83½rd lbs. per inch, it carried 16.65 H.P. without slip at 697 feet per minute, but slipped 5.71 per cent. with 17.28 H.P., and then off.

A first-class rubber belt of same dimensions, weighing 37 lbs., showed *no slip* in any test until it finally jumped the pulleys, giving 8.07 H.P. at 725 feet per minute, with 43½rd lbs. strain; 13.68 H.P. at 660 feet per minute, with 62½ lbs. strain, and 18.61 H.P. at 650 feet per minute, with 83½rd lbs. strain, the last test starting the rubber covering. The variations in speed are due to the incapacity of the engine to carry these loads in addition to its regular work.

We now come to the cotton duck leather-lined belt already mentioned. This belt was a four-ply duck, with a soft leather lining cemented on, and weighed 37¼ lbs., of the same size as the others, but was ¼-inch thick, or  $\frac{1}{16}$ th inch duck and  $\frac{1}{16}$ th leather. It stretched 2½ inches with 43½rd lbs., and drove 10.80 H.P. without slip at 754 feet. With 12.4 H.P. it slipped 13 per cent., and then slipped off. With 62½ lbs. per inch strain it carried 11.88 H.P. without slip at 747 feet per minute, stretching 2¼ inches.

It carried 19.40 H.P., with 14.7 per cent. slip at 711 feet, and then slowed down the engine without going off. With the steam increased to 83½rd lbs., it carried 16.98 H.P. without slip at 711 feet per minute, and with 21 H.P. and 9 per cent. slip slowed down the engine to 690 feet, and the test was stopped with the belt still on. All these last tests were on iron pulleys. We now changed to the wooden ones, and got 27.87 H.P. without slip, stopping the engine.

We then split the belt down to 8½ inches, or 117 lbs. per inch, and on the same pulleys got 25½ H.P., with 1 per cent. slip. Changing to paper pulleys, we got 25.30 H.P. *without slip*, but exhausted our power as before, and on applying the scales found the belt to still hold its strain of 1,000 lbs. As will be seen from the above tests, we could not get higher speed with these belts, so we took a five-ply belt of same kind, 5 inches wide,  $\frac{1}{16}$ th inch thick, 31 feet 2 inches long, weighing 19 lbs. This stretched 2¼ inches under a strain of 77 lbs. per inch, and gave 7.20 H.P. on iron pulleys without slip at 754 feet per minute. With 9.80 H.P. it slipped 3½ feet, and with increased load slipped off. On wooden pulleys it drove 10.19 H.P. without slip at 711 feet per minute, or at the rate of 348 feet of belt per minute for a horse-power to each inch. We then put back the iron pulleys and increased the strain to 117 lbs. per inch, and got 10.29 H.P. without slip at 718 feet, and 12.63 H.P. at 698 feet, with 5.65 per cent. slip. We then put on a larger pulley to increase the speed, and under the same strain got 18.62 H.P. without slip at 1,301 feet per minute, and

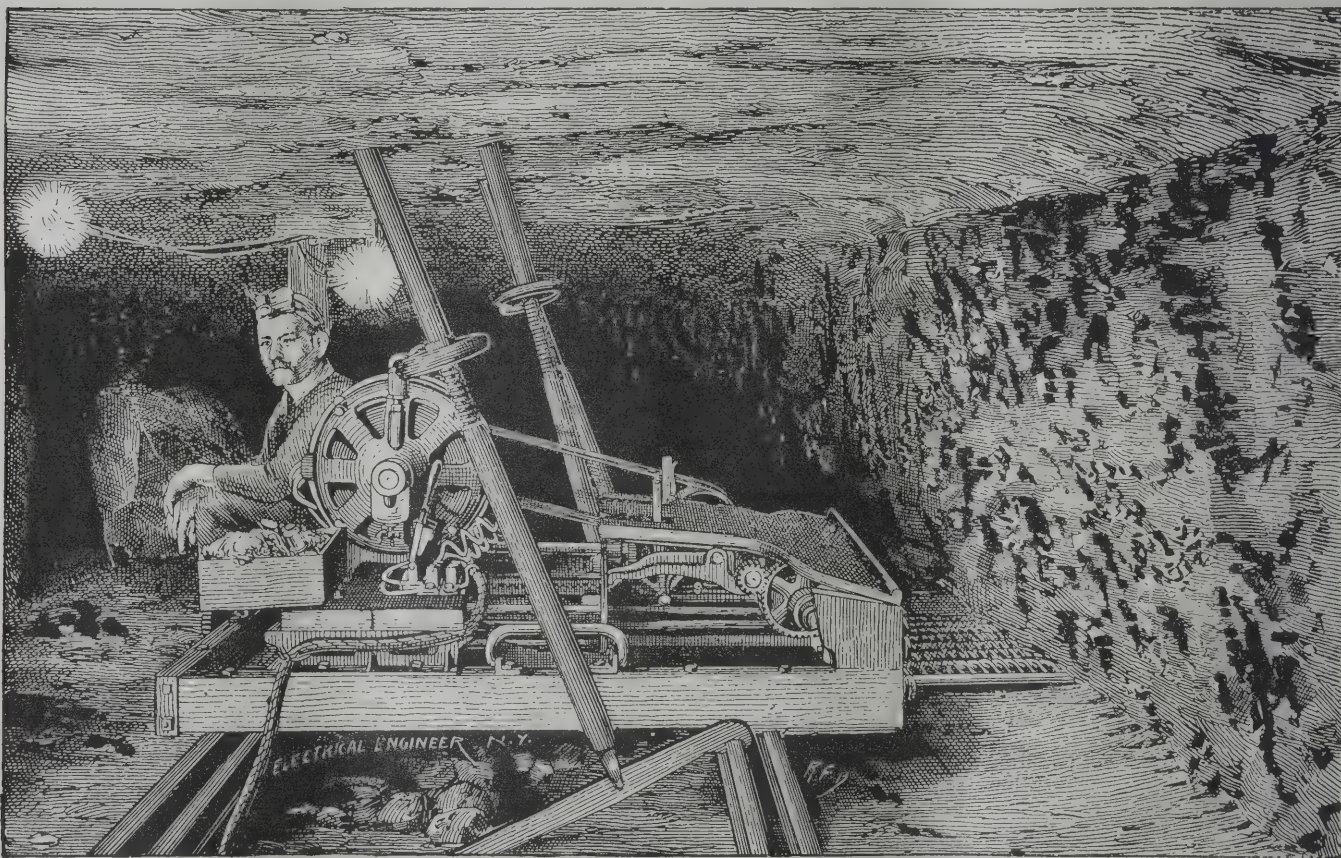

24 H.P. with 1.50 per cent. slip at 1,276 feet, 24.59 H.P. with 3.10 per cent. slip, and 24 H.P. with 5.50 per cent. slip at 1,222 feet per minute, slowing down the engine so that we could not continue the tests. These last two tests, however, go to prove that the slip does not increase with the velocity, and the last three were all stopped in good order, with the belts still on the pulleys. I think they go to prove that a strong light-woven belt, with a leather lining, if the cement is perfect, will be the belt of the future for all magneto-electric machines, as they combine great strength with light weight and great clinging properties.

I do not propose to enter into any discussion which may involve patent rights, but will simply say that while these cotton-leather belts tested were made by the Underwood Manufacturing Company, a very promising belt of the same materials is also made by the Page Belting Company, of Concord, N.H., differing in construction thus: Two canvas belts are used, meeting in the centre, with a single leather lining, which acts as a hinge, and permits the belt to adapt itself closely to a coned pulley.

that no metallic part is exposed. All wood work of the switches is made thoroughly waterproof and the switch handle is detachable and carried by the motor man. This prevents the switch being tampered with by meddlesome persons.

The wire used in these mines is all of the Clark rubber-covered special mine finish type, and all wire connections are made with McIntire connectors. All wood work is made waterproof with P. & B. compound. The coal cutting motors in the rooms are connected to the main line by a specially made insulated flexible cable, which can be coiled on a special reel and taken to another room in a few minutes. This cable when in use is supported by glass hook insulators made for this purpose.

Six "Hercules" coal mining machines, with 3 H.P. Tesla motors mounted thereon, as shown in the engraving, are now in operation in these mines. The machine and motor complete weighs about 1,000 pounds and is easily handled and shifted from room to room by one man. A specially designed truck is used in conveying machine from one room to another.

TESLA MOTOR DRIVING HERCULES COAL MINING MACHINE.

## AN ELECTRIC COAL MINING EQUIPMENT.

A HIGHLY interesting electric plant was recently put in operation in the First Pool Monongahela Gas Coal Co.'s mines at Willock Station, Pa. This electric equipment was designed and installed by the Mill and Mine Electric Equipment Co., of Pittsburgh, Pa., under the supervision of Mr. W. A. Giles, general manager and electrical engineer for the company, who has supplied the following interesting particulars regarding the plant to the *New York Electrical Engineer*.

The power plant consists of two 12 x 20 Carter engines and one 30 H.P. 3-wire, 4-pole Westinghouse self-exciting, alternating generator. All switches, meters, &c., are mounted on a switchboard in a most convenient location to be easily handled. The voltage on the main line is about 300 volts. Inserted in the main line at convenient locations are several specially designed mine switches with safety catch attachments, and all switches used in these mines are so designed

These machines, by means of a set of gang bits or augers, make an undercut 3 inches high, 36 inches wide by 42 inches deep. One man with this machine will average 40 cuts, or about 43 tons of clean cut coal in 10 hours. This is equal to the product of 12 to 14 pick miners.

The ventilating outfit in this mine consists of a 12 feet Pollock fan, with a capacity of 30,000 cubic feet per minute. It is situated at the bottom of a shaft 75 feet deep, and is so arranged that the fan can be changed from an exhaust to a blower in five minutes. This fan is also run with a 3 H.P. Tesla motor.

The pumping outfit consists of a centrifugal pump of a capacity of 90 gallons per minute, mounted on the same truck with 3 H.P. Tesla motor and connected to the same by means of a belt. This pump and motor can be taken to any part of mine and connected to the power line in a few minutes.

These mines have an incandescent electric light plant, consisting of a United States 300 volt, automatic incandescent dynamo, running 150 Sawyer-Man lamps,

mounted in special waterproof mine sockets with rubber insulating joints. These lamps are connected in loops of three in series across the main circuit, and placed along the main entry at a distance of 80 to 90 feet, and three 16-C.P. lamps are placed in each room. This gives perfectly satisfactory illumination and demonstrates the great importance of better light in coal mines.

The following record shows the large amount of work which can be accomplished with but a few machines. Indeed it has been demonstrated that they can work faster than the rooms can be cleaned up of the coal which is brought down. The record, which is taken from the company's books, extends from July 1st to August 8th, and each cut represents about 1<sup>1</sup>/<sub>10</sub> ton of nut coal.

	No. of machines at work.	No. of cuts made.	No. of machine- hours run.
July 1 ... ..	5	113	35 <sup>1</sup> / <sub>2</sub>

The Mill and Mine Electric Equipment Company is now putting a similar equipment in Mr. Frank Armstrong's Summer Hill Mines at Woodville, Pa.

OUR OCEAN TELEGRAPH MONOPOLIES.

THE *Economist* in its issue of the 23rd ult. has an interesting article, under the above heading, which is as follows :—" We have received a copy of a petition to the Queen on behalf of the British merchants, bankers, shipowners and others carrying on business in Hong-kong, China, and Japan, praying that steps may be taken to set aside a secret convention between the Eastern Extension and Great Northern Telegraph Companies and the Chinese Government, whereby it is understood that a rate of \$2 per word shall continue to be charged, even after the Chinese land lines have effected a junction with the Russian, upon all messages to Europe west of Russia itself. It is argued that thereby a monopoly hurtful to British interests in the East will be maintained, and that Russian merchants will be placed in an exceptional position of favouritism by contrast with the rest of Europe. We are quite aware that the Eastern and Eastern Extension Companies, by agreement with the Great Northern, the Indo-European, and other companies, have taken all precautions available to secure their monopoly and avoid the cutting down of rates. We do not raise an objection to such combination; this is an age of combination. But we must be permitted to welcom-

counter-combinations. The agitation which has ended in an agreement for the reduction of the Australasian cable rates would scarcely have succeeded\* had the Pender companies not desired to take the wind out of the sails of the proposed Pacific cable, which was favoured by Canada, by Queensland, in some degree by New Zealand, and, after a reserved fashion, by the Home Government. When that reduction comes into force, the China and Japan rates will be the highest in the East, and naturally the China merchants feel themselves aggrieved. On the other hand, the cable companies argue that they established the system when the Eastern merchants were only too glad to welcome them on any terms; that they obtained rights which must not be ignored, and that after 20 years the Eastern Company is only paying 6<sup>1</sup>/<sub>2</sub> per cent. upon its ordinary shares, and the Eastern Extension only 7 per cent. Neither the Australasian nor the China merchants, they say, have a right to depreciate their property. Rates, in fact, would remain without alteration indefinitely were it not for agitation backed up by prospects of competition; and the companies, as we have said, strive, by all means in their power, to defer that evil day by repressing competitors whenever they show signs of presenting themselves.

"It is worth while, however, examining into the claims which the various cable companies put forth to an adequate remuneration on their invested capital. Six and a-half and seven per cent., though very fair rates as times go, are nothing extraordinary in themselves upon investments of twenty years' standing. But it must be remembered that these are the rates payable on a watered capital, and that they represent considerably higher returns upon the money actually put into the cables. It is now seventeen or eighteen years since the seven companies connecting this country with the East were amalgamated into two; and those amalgamations were effected in the following manner :—

	Share capital.	Converted per cent.	Capital after conversion.
Anglo-Mediterranean ... ..	£430,000	200	} Eastern Telegraph Co.
Falmouth and Malta... ..	760,000	120	
Marseilles, Algiers, and Malta ... ..	200,000	100	
British Indian ... ..	1,187,500	120	
	£2,577,500		£3,397,000
British Australian ... ..	540,000	110	} Eastern Extension Co.
British Indian Extension... ..	460,000	150	
China Submarine ... ..	525,000	110	
	£1,525,000		£1,997,500

"Thus, the Eastern capital was watered to the amount of £819,500, and the Eastern Extension to the amount of £472,500, and a dividend of 6<sup>1</sup>/<sub>2</sub> per cent. on the Eastern capital should be read as over 8<sup>1</sup>/<sub>2</sub> per cent. on the original capital, while 7 per cent. on the present Extension capital means over 9 per cent. on the capital prior to its being watered. Beyond this, these companies have worked themselves into a very strong position by not dividing to the full extent profits legitimately earned. When the Eastern Company was compounded in 1872 out of the four lines already referred to, their combined reserves only reached £70,000, whereas at the present time the reserve is £600,000, while extensive additions to the system have been effected out of revenue. We do not say that this conservative policy has not been a wise one. Far from it, we consider that the best interests of the proprietors have been consulted. But the dividends paid have been no guide to the profits made, and if requisite, the tariffs could be much reduced without affecting the payments to the shareholders. The Eastern Extension Company have even larger reserves, reaching to as much as £700,000, and this company has likewise made large additions to the cables out of revenue.

"We have, so far, dealt only with the Eastern companies. But it is worthy of remark that the 'stock-watering' in the instances of the Atlantic cable companies was carried to still greater lengths. Not to

\* It will be remembered that the proposed agreement has fallen to the ground.

go back to the original amalgamation of the Anglo-American and Atlantic Telegraph Companies, there was the amalgamation of 1873, when the following additions were made to the capital invested :—

	Original Capital. £		Anglo-American Capital. £
Anglo-American .....	1,675,000	.....	2,548,450
French Atlantic.....	1,650,000	.....	3,451,550
Newfoundland .....	864,520	.....	1,000,000
	4,189,520	.....	7,000,000

"Anglo-American stock now stands at about 50 per cent. discount, but we do not consider this to represent any discount upon the original investment; and we believe that as regards the old Anglo-American capital as it stood prior to 1868, it represents a substantial premium. But without seeking to make too much of those waterings, which occurred sufficiently long ago to have been almost forgotten, it may be pointed out that reductions in tariff are not the loss to the companies that Sir John Pender would argue. In 1868 the Atlantic Company was charging £5 5s. for 20 words, or, say, 5s. 3d. per word on a long message, whereas nowadays 1s. per word brings a far greater revenue. Only, the Anglo-American Company now obtain considerably less than one-half the Atlantic traffic, whereas years ago they had a monopoly such as Sir John Pender rules over now. Fair reductions of tariff are sure in a year or two to bring their own recompense, and if the Eastern Extension and Great Northern Companies seek to disarm opposition and competition, they must be alive to meeting the requirements of modern business."

## REVIEWS.

*Leçons sur L'Electricité professées à l'Institut Electro-Technique Montefiore annexé à l'Université de Liège.* Par ERIC GERARD. Tome II. Canalisation et Distribution de l'énergie électrique; Applications de l'Electricité à la production et à la transmission de la puissance motrice à la Traction, à l'Eclairage et à la Metallurgie. Paris: Gauthier-Villars et Fils, 55, Quai des Grands-Augustins.

We decidedly like this second volume better than the first, as there is more originality in its composition and the information given is very fairly up to date, a point of great importance, seeing the rapid changes which are continually taking place in the science. The author again gives very general information, describing systems employed by various countries, and methods, apparatus, &c., devised by inventors of every nationality. In referring to overhead wires, he gives in full the Board of Trade regulations with regard to the same. Theory is not entered into largely, but when it is considered necessary it is judiciously curtailed. Altogether the writer has done his self-imposed work with great discretion, and has produced a volume which should prove of great use to the pupils of the Institute of which he is director, and to others.

*Illustrated Catalogue and Formulae.* CROMPTON AND COMPANY, LIMITED, Chelmsford and London.

This is an excellent little pocket-book, and although, of course, it is actually issued for advertisement purposes, it is a book which should prove useful to everyone who has anything to do with electric lighting, as it enables estimates, &c., to be drawn up with great facility. It is well worth the one shilling charged for it.

**Thunderstorms to Order.**—A Chicago electrical trading company professes to be able to supply anything in the way of electricity from a push-button to a thunderstorm.

## NOTES.

**Lighting a Flour Mill.**—Messrs. Ernest Scott & Co., electrical engineers, Newcastle-on-Tyne, have obtained the contract for the complete electric light installation for the new flour mill at Dunston, being built by the Co-operative Wholesale Society. This mill when completed will be one of the largest in the kingdom, if not the largest, and the electric light plant which is being put in in duplicate will consist of two 400-light "Tyne" compound-wound dynamos running at 600 revolutions per minute, and 466 16-C.P. incandescent lamps. The arc light installation will consist of one 9-unit "Tyne" compound-wound dynamo and 10 ampère "Tyne" arc lamps in strong water-tight lanterns with reflectors. We hear that Messrs. Ernest Scott & Co. have a considerable quantity of work in hand of all descriptions, including a large contract for the lighting of Messrs. Arthur & Co.'s works in Glasgow, in which two 400-light "Tyne" dynamos will be used. They are also lighting Messrs. John Bright & Bros.' Mills at Rochdale, the new works of the *Bolton Evening News*, and the cold meat rooms of the Northern Counties Ice Company.

**Electric Lighting at Hastings.**—A public meeting for the purpose of considering the electric lighting proposals of the Hastings Town Council was held last week, under the presidency of Mr. H. Chapman. The chairman ridiculed what he described as the electric light "job," and which he feared would be carried into effect unless the ratepayers spoke out. A committee was appointed to request the mayor to call a town's meeting.

**Ship Lighting.**—The contract for lighting four new steamers being built for the Manchester, Sheffield and Lincolnshire Railway Company has been given to Messrs. Paterson and Cooper. Two of these are in hand at Earle's shipyard, Hull, the other two at Swan and Hunter's, Newcastle. Messrs. Paterson have on hand besides the above the ss. *Innamincka*, *Tuskar*, *Arranmore*, *Garnet*, *City of Dundee*, and H.M. training ship *Empress*.

**Lewes Lighting.**—At a recent meeting of the Town Council an estimate for lighting the town electrically was received from the Gülcher (New) Electric Light and Power Company, Limited, based on the following lines. A complete set of plant and apparatus for 240 16-C.P. incandescent lamps will be provided. These lamps may be distributed in any manner desired over 7½ miles of streets. Incandescent lamps of a higher candle-power may be substituted where desired, the total number of lamps being in proportion to the candle-power, i.e., a 32 C.P. incandescent lamp takes the place of 2 16-C.P. lamps, a 48 or 50 C.P. takes the place of 3 and so on. Modifications in the incandescent lamps of this kind will not affect the cost of the installation. Arc lamps of 2,000 C.P. nominal can be supplied to take the place of 12 16-C.P. incandescent lamps, but every such substitution will increase the total cost of the installation by £15. The company undertake to start the running within 16 weeks after date of order. The estimate does not include the supply of lamp-posts as it is presumed the present gas lamp-posts will be utilised for carrying the incandescent lamps. Since a continuous supply of current is not necessary the company feels quite confident that a single set of generating plant is all that is needed to meet the case, but for absolute security recommend the advisability of duplicating the generating plant, this course would entail a further expenditure of £500. The consideration of the matter was adjourned.

**American Theatre Lighting.**—The Duquesne Theatre at Pittsburg, Pa., is to be lighted throughout by electricity with something over 800 lights. Though not as large as some, it is claimed that this will be a model plant.

**Electric Lighting in Germany.**—The municipal councils of German towns would appear to prefer the carrying out of electric lighting schemes rather than place these in the hands of companies. Cassel is to have an installation commencing with 3,000 incandescence lamps; Breslau has voted £50,000 for an illumination to begin with 8,000 lamps, the central station being built to supply 30,000; Cologne has determined on an installation of 12,000 lamps of 16 candles; and at Dusseldorf the corporation has decided on an illumination of 20,000 incandescence lamps at a cost of £100,000.

**Electric Light in Siam.**—Vice-Consul Stringer, of Bangkok, states that last year a Siamese company, called the Siam Electric Light Company, was formed, two of the leading princes being secretary and treasurer respectively. An agreement was entered into between certain Siamese of high rank, of whom the present head of the Treasury is the leading spirit, and the Brush Electric Light Company, by which the latter engaged to supply engineers and material for the establishment of a system of electric lighting in the city within a radius of four miles from the central station in Bangkok. There being no supply of gas, except on the road in front of the Royal Palace, and the thoroughfares being but dimly lighted with oil lamps, the employment of electricity will no doubt place Bangkok in a position superior to that of most Oriental towns. The owners of large rice and saw mills also, many of whom keep their works going day and night, will find the light a great convenience. The shares of the company are now quoted at a premium.

**Electricity for Spectacular Effects.**—A dynamo and a complete electrical plant will be carried by "The Limited Mail" theatrical company, to produce the telegraph and other effects in that play.

**The Electric Light at Godalming.**—This, it will be remembered, was the first town in the United Kingdom to adopt electricity for public lighting. The installation was not a success, and recourse was had again to gas. Now, with a view of giving electric lighting another trial the members of the Town Council are going to visit Bath and inspect the installation there.

**The New York Phonograph Company.**—The various branch phonograph companies of New York have been combined in one corporation, named the New York Phonograph Company, the President of which is J. P. Haines.

**Woodhouse and Rawson United, Limited v. Appleton, Burbey and Williamson.**—A cricket match, between elevens representing the above firms, was played on Saturday last, at Raynes Park, which, after a very exciting game, ended in a victory for the former by one run.

#### Interruptions and Repairs to Submarine Cables and Land Lines:—

Section.	Interrupted.	Repaired.
Cable Hongkong—Foochow ...	21 July, 1890,	26 July, 1890.
" Suakim—Perim ...	9 May	29 "
" Banjoewangie—Roebuck Bay, 11 July	"	2 Aug. "
" Para—Maranham ...	24 "	21 "
Land Line Moulmein—Bangkok	28 "	30 July "
" " Saigon—Bangkok ...	9 Aug.	10 Aug. "
" " " "	13 "	14 "
" " " "	21 "	22 "

**Electrical Nomenclature.**—In a communication which appears in *Industries* of August 29th, Mr. James Swinburne criticises the proposal made by Prof. J. A. Fleming of using the word "hen" (derived from the name of Henry) as the unit of self-induction. The article is but a short one, yet in it there is space to discuss such terms as secohom, parasangs, gilb, gil, lig, dun, nud, scot, frank, cavs, vacs, &c. If this sort of terminology is continued much further, the electrical engineer of say a decade hence will be obliged to carry about with him a technological dictionary.

**Accumulators in Telegraphy.**—Accumulators have been employed to a considerable extent in the central telegraph station at Berlin since the month of October, 1888. The administration set up 25 batteries of Tudor accumulators. The current is distributed in three directions and serves 68 lines, on which 41 Morse and 27 Hughes instruments are worked. The three systems comprise one of 36 wires at 34 volts, another of 12 wires at 40 volts, and the third of six wires at 60 volts, with one wire at 80 volts. The installation has proved so successful that a fourth system is in course of being supplied with current in the same manner. The batteries are capable of working for one month, but are generally recharged every 10 days by means of a Siemens dynamo worked by a gas motor of 8 H.P.

**Telephone Wire.**—It is reported that the French Administration of Posts and Telegraphs has decided to replace the phosphor bronze wires on telephone lines, and the iron wires on telegraph lines, with "Martin" wire, the results of very thorough experiments having conclusively proved the great superiority of the latter. This wire consists of a steel core covered with soft copper.

**The "Peral."**—The following paragraph appears in *Industries* of August 29th:—"The Government will soon publish the official report of the Naval Commissioners appointed to report on the trials of the submarine vessel *Peral*, lately made in Cadiz Bay. It seems that the report, though drawn up in very flattering terms for Lieutenant Peral, nevertheless recommends the Government not to construct any vessel of this class, as the trials have proved that the vessel is unseaworthy, and that it does not offer the conditions required for submarine navigation, even on coasts and in fine weather."

**Cost of Accumulator Traction.**—The Société Française d'Accumulateurs Electriques have issued an estimate as to the cost of accumulator traction on their system. A line equipped with 40 cars would cost £40,000, including the whole of the plant at the generating station, but excluding the cost of the station building. Out of these 40 cars, four would be kept as reserve, and with 36 cars in daily service, they estimate the cost at 28 francs per car kilometre, or 4½d. per car mile. This figure includes the cost of maintaining the rolling stock (including depreciation of batteries) and fixed machinery, and the working expenses at the charging station. Each car would travel 74 miles daily. The actual results, however, on the Barking line, prove that enough has not been allowed for maintenance of batteries.

**Personal.**—We hear that Mr. Arthur C. Cockburn has now ceased to be connected with the Acme Electric Works, his future address being 22, Streatley Road, Brondesbury, N.W., where he will continue to practice as a consulting electrical engineer.

**A Chance for Inventors.**—A New South Wales correspondent to a New York electrical paper complains that there has not yet been introduced a really successful electric sheep-shearing machine. The want of one is badly felt in Australia.

**Electric Traction in Germany.**—The Berlin *Tageblatt* says that the question of electric railways is about to be taken up seriously in Germany.

**Siamese Telegraphs and Telephones.**—The Siamese telegraph service has lately been considerably improved. The department is under the control of a Siamese prince, and most of the *employés* are either German or French. New telegraph stations have been established at Rathburi, Petchaburi, and Bangtaphan. A system of telephones has been laid down in Bangkok, with connections and exchanges on both sides of the river. All the large firms and trading houses, and many private individuals, are subscribers.

**Music by Telephone.**—An experiment made in Berlin, on Tuesday, in transmitting opera music from the Opera House to the Urania Theatre of Science by means of a telephone was a complete success. It is hoped that it will be possible to make an arrangement with the telephone exchanges to furnish other places with music through the telephone.

**Gas by the Pennyworth.**—The Gas and Lighting Committee of the Bolton Corporation have just decided to make an experiment with a new kind of meter, strongly advocated by one or two of the labour representatives for the automatic supply of gas. In some quarters there is a strong aversion to quarterly gas accounts, and the result is that oil is used instead of gas, and to overcome this the Gas Committee have fitted in a few houses a meter which supplies gas on the same principle as the automatic sweetmeat machines—by placing a penny in a slot.

**The Telephone at Sea.**—The telephone has played an important part in the naval manoeuvres of the Swedish fleet. There is a telephonic post on board each vessel, and when lying at anchor they can telephone to one another by means of insulated conductors, which are run down the anchor chains and submerged. In Sweden, trading vessels arriving in dock are quickly connected by telephone to the nearest exchange.

**The Tory Island Cable.**—It has transpired that the opening of the Tory Island cable on Tuesday almost resulted in a fiasco, and the telegram to the Queen was very nearly not being sent at all. Previous to the ceremony, it was found that no communication could be had with the mainland from Tory Island, and on investigation it was discovered that the cable running over the Horehead Bridge was broken. The broken ends of the cable were found lying in the stream, and the connection was established just in time.

**Microphonic Phenomena.**—The series of papers which we have recently published, from the pen of Mr. A. M. Tanner, will, we feel sure, be much appreciated by experimentalists, and his contribution on page 279 will specially appeal to the sympathetic interest of Prof. Hughes. Mr. Tanner has done good service in unearthing the researches of men now forgotten.

**The Annealing of Copper.**—The paper by Mr. Cummins, which we print on another page, demands the attention of all manufacturers of copper.

**Gas versus Electric Light.**—We wonder what complexion the gas journals will put upon the results which M. Paul Hoho describes on page 260? Is it possible that the author may have based his conclusions on false premises; if so, we shall soon see them opposed by our contemporaries.

**Fatal Electrical Accidents.**—New York, August 30th.—A fatal accident, due to electricity, occurred to-day at Wheeling, West Virginia. Two men stepped upon a wire connected with a powerful dynamo, and fell dead. People ran to raise them, and two who were lifting the bodies from off the wire sustained severe electric shocks.

Cincinnati, August 30th.—A fatal electric light accident occurred here to-day. A lineman employed by the electric light company of this city inadvertently grasped a live wire, and was instantly killed. It was found that the unfortunate man's hand had been almost burnt off.

It seems from these telegrams that although electrical execution is said by the opponents of the measure to be quite unreliable, the number of inadvertent fatalities in the States show no signs of diminution.

**Companies Meetings.**—We desire to call attention to the report of the Brush Electrical Engineering Company, Limited. So far as one can judge, the conclusion of the directors seems to be well founded.

**The Telegraphists' Grievance in Dundee.**—Dundee telegraphists have passed resolutions condemning the new order stopping the increase granted to some of the classes until next year, and calling upon those who had participated in the increase to return all the money received.

**Belting.**—To all users of motive power, Mr. Webber's article on belting will be welcome, and perhaps it may be the means of bringing forth the experiences of belt users on this side of the water. Mr. Webber knows of but one exception to the old adage, "There's nothing like leather."

**New Arc Lamps.**—The Sperry Electric Company of Chicago has been granted a patent for an improvement in a single arc lamp, a simple adjustment which at once changes the lamp from an eight to a 16-hour one. The device can be applied to any arc lamp known on the market. This is, we imagine, the outcome of the litigation on double carbon lamps.

**Gas Explosion.**—An explosion of gas occurred on Monday evening last on the premises of Mr. J. W. Tacon, 277, High Holborn. The force of the explosion was of sufficient violence as to partially destroy the shop front, and damage the interior of the establishment, but happily the assistants and others in the place at the time escaped without injury. Mr. Tacon is only removed one door from an electrically lighted shop, having probably the oldest installation of any importance in the metropolis.

**The Late Cable Interruption.**—"The manager of the Telegraph Department informs us that the recent cable interruptions were caused by a very severe earthquake. The duplicate cable, which was repaired yesterday morning, was broken in three places within 65 miles of Banjoewangie. The other two cables are not yet repaired. The following telegram from the general manager of the Eastern Extension Company at Singapore has been received by Mr. W. Warren, the manager of the company in Australasia:—"In restoring duplicate cable Baly Straits ships found for a distance of 30 miles cable much broken and overlaid from effects of disturbances at bottom of ocean. Ship now at work on original Darwin-Java cable." The above extract from the Melbourne *Argus* of July 22nd, 1890, recently to hand, throws a little more light on the simultaneous interruption of the three cables to Australia. From this it appears that the cables were not only ultimately interrupted, but that the first cable repaired was found to be broken in three places; in fact, to quote from the leading article of the same paper on this subject:—"There is now unchallengeable evidence that the company made a serious mistake in running all its cables to Australia from one place, and that the fancied security in which we imagined ourselves to be reposing could only continue so long as an earthquake did not happen near the converging point. We have learned now that it is unwise to put trust in any single means of communication with Europe, and to all intents and purposes the Eastern Company's service is a single service, though the traffic, when all lines are working may be distributed over three routes. The connection at Banjoewangie represents the weakest link and governs the strength of the entire chain. Our interests demand that we must not be deprived of the means of swift correspondence even for a day, and it follows that the service which makes such an interruption possible is ill-suited to our requirements."

**Nalder Brothers and Company.**—The premises in Westminster that have been occupied during the last few years by Messrs. Nalder Bros. & Co. being now found insufficient for their rapidly expanding business, the firm has been obliged to take new works at 16, Red Lion Street, Clerkenwell. These are to be ready by November, and as they will be well equipped with new machinery, improved facilities will be afforded for turning out electrical work of all kinds.

**Contracts by Telephone.**—At the present day the telephone plays an important part in commercial affairs, and most mercantile men find it a great convenience in facilitating and accelerating business. But a recent American lawsuit goes to show that, handy as the telephone may be to business men, the convenience that it affords is not without its drawback. The case to which we—the *Machinery Market*—allude is this:—In an action brought in the United States Courts by the Paddock-Hawley Iron Company against Messrs. Pullis Brothers, it appeared that some iron was ordered by telephone, but that, when the bill was sent in, Messrs. Pullis Brothers demanded a reduction of some 10 per cent., in virtue of an agreement to that effect, which they said had been made by telephone. In reply to this, the plaintiffs asserted that there were only two members of their firm empowered to make such contracts, and that neither of them had heard of this telephonic communication until after this controversy had arisen. The Court held that, while a telephonic contract was as binding as any other, the same rule of evidence applied, and as there was not sufficient evidence to disprove the assertion of the plaintiffs, it was decided that the bill must be paid in full. This appears to be an equitable decision, founded on common sense, and simply serves to point the old moral, that all contracts should be reduced to writing. It is obviously as impossible to bring a telephonic contract into court as any other verbal one.

**Correction.**—In our last issue we referred in our "Official Returns of Electrical Companies" to the business carried on by Messrs. Head, Wrightson and Company, Limited, at South Shields; it should read, "at Stockton-on-Tees."

**Dissolution of Partnership.**—The firm of W. Mackie and Chalmers, electrical engineers, Turk's Head Yard, Turnmill Street, Clerkenwell, has been dissolved by mutual consent, as and from November 30th, 1889. All debts due to and owing by the firm will be received and paid by Matthew William Walbank Mackie.

**Experimental Electric Lights.**—The exhibition of experimental electric lights from points visible in the Needles Channel will be resumed at intervals during the present month.

**Electric Lighting at Portsmouth.**—At Tuesday's meeting of the Portsmouth Town Council, a special committee was appointed to prepare a report as to the best mode of adopting the Electric Lighting Acts. The palatial new Town Hall is already lighted by electricity, and it is known that a strong opinion exists among many of the members of the Corporation that the time has arrived when the municipality should offer to supply the electric light to the inhabitants. On the other hand, considerable opposition is certain to be offered to any such scheme, as the gas interest is somewhat strongly represented in the Portsmouth Town Council.

**University College, Bristol.**—The calendar for the ensuing session, commencing 1st October, is now published. The course of electrical engineering covers three sessions and includes training in electro-technics, mathematics, physics and chemistry, with continuous laboratory work and practice in testing. It is recommended that, inasmuch as an electrical engineer must, in addition to his knowledge of electricity, have a thorough acquaintance with practical engineering, all students who enter for this branch should arrange with some firm either of electrical or of mechanical engineers for a course of training in engineering work. The college authorities have lately arranged for students to spend one or two terms of six months in works during their college career.

**Edinburgh International Exhibition Notes.**—A correspondent sends us the following clippings:—A trip to Slateford in one of the electric launches was then undertaken, and this gave unfeigned pleasure to everybody. For a wonder it wasn't raining, and the atmosphere was clear enough to afford a glimpse of the Forth Bridge in the distance and of the lovely scenery around. The trip out and home occupied exactly 24 minutes. Again, it was feared that Glasgow could derive no benefit from the invention under inspection, for where, except on Finnieston Loch, could electric launches be floated without risk of poisoning the passengers? After dinner the accumulator car used on the Birmingham tramways, and exhibited by the Electric Construction Corporation, was inspected minutely, for here (Bailie Paton declared) was to be found the ultimate solution of the tramway difficulty. The Glasgow gentlemen seated themselves in the car, and listened with evident appreciation to the explanations which Mr. Bennett, standing in the midst, gave. Some of them, and especially Bailie Paton, had evidently studied the subject more than superficially, and from the remarks made it seems clear that electric traction is likely to have a fair field in Glasgow as soon as the Corporation acquire control of the trams. Neither at Glasgow in 1888, nor at Paris last year, was there any example of electric traction, and the authorities of our present exhibition have certainly reason to be proud of the display made. Several of the visitors expressed their astonishment at the extent and scientific character of the exhibition, not unmingled with remorse at having, in some mysterious way, been led to undervalue and depreciate its importance. "Certainly," said one of them, "we had the switchback, but nothing else of importance (?) in the railway line." On account, no doubt, of the existing tramway problem in this city, the attention of the Glasgow magistrates was on Tuesday specially directed to the illustrations of electric traction, in which the exhibition is so rich. No previous exhibition anywhere has boasted more than one example of electric traction; here we have three systems—pick-up current tramway, Telpher, and launch—in actual operation, while a fourth, the accumulator tramway, is shown quiescent in the machinery hall. A successful run was made by the car "Faraday" from the Caledonian end, passing the switchback station without stopping, the whole distance of half a mile being covered in three minutes. At the bandstand end Mr. Bennett explained the system in detail to Bailie Paton and other members of the Tramway Committee. The opinion expressed was that, although good enough for America, the overhead conductor system was not ornamental enough for Glasgow. The next jaunt was on the telpherway, two "specials" being run for their accommodation. On entering the trains there was quite a display of French politeness, each gentleman evidently being afraid of offending his neighbour by taking precedence. However, every one's modesty was at last overcome, and nearly the whole Corporation of Glasgow, Lord Provost, Bailies, and Councillors, were safely suspended on the wire rope with nothing but thin air between them and the daisies. The imagination stands appalled at the consequences of an accident at that moment. St. Mungo would have been like Edinburgh after Flodden, but with ne'er a Provost to comfort her. Happily, the tour was accomplished without a hitch. As the cars swung to and fro when rounding the curves, one could not help thinking that the prayer, "Let Glasgow Flourish," was being answered before one's eyes. It was the general opinion that the Telpher would not do for Glasgow either, except perhaps along the Broomielaw.

**An Electric Insurance Company.**—The Electric Mutual Insurance Company, of Boston, Mass., undertakes the whole risk on stations at fair rates, and return the profits at the expiration of the policy. "It belongs to no boards," it writes. "It makes its own rates. All of its directors are prominent electric light men. It is the electrical industries' own company. It also insures lamps, converters, meters, &c., outside of the station."

**Proposed Lighting of the Manchester Town Hall.**—At the ordinary meeting of the City Council, on Wednesday, Mr. Gunson moved:—"That the Town Hall Committee be instructed to report as to the best means of remedying the present unsatisfactory condition of the ventilating and heating arrangements of the Council Chamber and State rooms, as well as the various committee rooms and offices in the Town Hall; and also as to the advisability of the introduction of an installation for electric lighting." Dr. Simpson seconded the motion, which was accepted by the Mayor on behalf of the Town Hall Committee.

**A Portable Electric Safety Mining Lamp.**—"I have" says M. G. Trouvé, in presenting his memoir to the Académie des Sciences, "to recall to your minds that I have already, in connection with the Saint-Etienne disaster, had the honour to produce before you the first portable electric safety lamp. This lamp is in use in the State powder magazines at Sevrans-Levry and Ripault, as also in the artillery and engineering schools of Versailles, Toul, Verdun, Epinal, Belfort. It is also used by the Parisian Gas Company, and, exclusively of any other, by the Paris fire brigade and the Italian Navy. It furnishes a current of 1.5 ampères and 11.4 volts, *i.e.*, 17.10 watts, lasting three hours, = 51.30 watt-hours. This energy corresponds to an intensity of 4.2 candles for three hours, or of one candle for 11 to 13 hours, an illumination far superior to that of ordinary mining lamps. I am therefore in a position to affirm that this portable electric safety lamp will be found of equal service in mines as it has been to the firemen of Paris, the gas company, &c."

**Copper.**—Under this heading, a financial contemporary speaks at great length on the present condition of the copper industry. The market, now so buoyant, was certainly in a low state during the greater part of 1889, considering that the price of a ton of copper seldom got above the forties. Even when this year opened, the effect of the French Syndicate policy was very apparent, and it was not until there came visible signs of the diminution of the hoarded supplies that the market became firm. Now, however, things are in a very good state, and there is every appearance of a strong market at £60 per ton. Last year there were certainly handsome dividends paid by at least two prominent copper companies, and there is every likelihood that things will be much better this year than last. It is interesting to note the doings of the Copiapo Company. Last year was very nearly its last. There came on the top of the smash of the French Syndicate, a collapse of one of the mine shafts, a misfortune the result of which can scarcely be calculated. In spite of this, however, the shaft was made good, and it actually contrived to pay a respectable dividend of  $6\frac{1}{2}$  per cent., a very creditable wind up for the year 1889.

The *Pall Mall Gazette* says:—"In copper the rise in price which has been going on for some time past is not so much due to speculation as to a legitimate increased consumption with a falling off in the supply. The rise in price, brought about by the manipulation of the market by the French syndicate, so increased the production, and stocks were multiplied at so rapid a rate, that the copper combination found that it had committed itself to a task which it was unable to carry out. Hence the well remembered breakdown of last year. After the collapse the price of copper was, for a time, as low as £35 per ton, and most people thought that it would be years before the large surplus stocks which had accumulated would be disposed of, and the market right itself. But as the rise in price increased production and curtailed consumption, so the heavy fall led to a curtailment of production and increase in the demand, so that there has been a gradual diminution of stocks, until there is now but a small quantity in hand. Here, then, it appears that the recent rise in price is justified, and will be maintained."

**The Telegraph Cable Question.**—The *Daily Chronicle* of September 2nd says, in an evidently inspired "Note":—"The refusal of the Chancellor of the Exchequer to join in the subsidy to the Eastern Extension Telegraph Company, or to share in the guarantee which is necessary to secure the further reduction of the rates, has caused much comment in business circles in Adelaide, and while the parsimony of the Imperial Government is strongly condemned, it is pointed out that the South Australian Government will probably benefit by the refusal, because the Imperial Government must now decline to assist with the subsidy for the proposed Pacific cable, which, if laid, would probably take away a good deal of the telegraph business at present proceeding *via* Port Darwin." As regards the question of the subsidy for the proposed Pacific cable, "the wish was," of course, "father to the thought." There is, however, no doubt whatever that the late interruptions of communications have set people thinking that a Pacific cable is the only way to secure freedom from the disastrous effects of earthquakes in the Java seas.

---

#### NEW COMPANIES REGISTERED.

**Sheffield Telephone Exchange and Electric Light Company, Limited.**—Capital £100,000, in £10 shares. Objects: To take over the undertaking of the existing company of the same title, incorporated on the 11th September, 1888. Signatories (with 1 share each): \*J. Tasker, \*G. Senior, \*G. Friklin, C.A., Wm. Johnson (engineer), T. G. Shuttleworth, C.A., R. E. Tasker, \*W. Tasker, all of Sheffield. The signatories denoted by an asterisk and J. Gamble are the first directors. Qualification, 20 shares. Remuneration, £300 per annum, divisible. Registered 28th ult., by J. B. Roberts, 12, Coleman Street, agent for G. J. Simpson, Solicitor, Sheffield.

**Freedman Battery Company, Limited.**—Capital £2,000, in £1 shares. Objects: To acquire the interest of Charles H. Freedman in an invention of which no particulars are given in the registered documents. Signatories (with 1 share each): \*E. F. Wyman, 74, Great Queen Street, Lincoln's Inn; T. F. Baker Evans, Anerley Park; \*C. H. Freedman (electrical engineer), 13, Montague Place, W.C.; T. Douglas Murray, 33, Grosvenor Square; F. Suter (electrical engineer), 6, Ospringe Road; M. Davis, Montreal; H. H. Cooper (electrical engineer), 100, St. Donatt's Road, New Cross. The signatories denoted by an asterisk, and T. F. B. Evans, are the first directors. After 10 per cent. per annum dividend has been declared, the directors may receive such remuneration as may be voted them by the company in general meeting. Registered 1st inst. by Wm. Webb & Co., 6, Essex Street.

---

#### OFFICIAL RETURNS OF ELECTRICAL COMPANIES.

**South of England Telephone Company, Limited.**—The annual return of this company, made up to the 1st August, was filed 1st September. The nominal capital is £400,000 divided into 300,000 ordinary shares of £1 each, and 20,000 preference shares of £5 each, the whole of which are taken up, the ordinary shares being considered fully paid. Upon the preference shares £3 10s. per share has been called and paid, the paid-up capital thus being £70,000.

**Telephone Company of Austria, Limited.**—The annual return of this company, made up to the 14th ult., was filed 23rd ult. The nominal capital is £200,000 divided into 20,000 ordinary and 20,000 preference shares of £5 each. The shares taken up are

11,703 ordinary and 6,558 preferred, upon which the full amount has been called. The calls received amount to £33,540, and £57,765 is considered as paid upon 11,553 ordinary shares.

**Sheffield Telephone Exchange and Electric Light Company, Limited.**—At an extraordinary meeting of this company, held at the offices, Commercial Street, Sheffield, on the 14th July, it was resolved to reconstruct, and for such purpose to wind up voluntarily. Mr. Thomas George Shuttleworth, of Sheffield, chartered accountant, and Wm. Johnson, of Sheffield (the secretary), being appointed liquidators.

**Chili Telephone Company, Limited.**—The annual return of this company, made up to the 22nd ult., was filed 29th ult. The nominal capital is £250,000, in £5 shares. 40,000 shares are taken up, upon which the full amount has been called and paid.

**Nonpareil Electric Syndicate Company, Limited.**—The registered office of this company is at 2, Victoria Mansions, Westminster.

## CITY NOTES, REPORTS, MEETINGS, &c.

### The Brush Electrical Engineering Company, Limited.

In the first annual report, to be presented to the shareholders at the general meeting of the company to be held at Cannon Street Hotel, London, on the 8th September, 1890, at 12 o'clock noon, the directors submit the balance sheet and profit and loss account, made up to 30th June last.

It is as follows:—

The company was registered on the 10th August, 1889, and the business of the Anglo-American Brush Electric Light Corporation, Limited, was taken over as from the 1st August, 1889, and that of the Falcon Engine and Car Works, Limited, as from the 14th June, 1889, and the accounts made up to the 30th June last are for the periods embraced by these dates. The arrangements for carrying on the business of the Australasian Electric Light and Power Company, Limited, were not completed until much later, and the accompanying accounts do not include any return of business effected by the Australasian branch.

The profit and loss account shows a gross profit of £36,698 16s., and after deducting all standing charges, maintenance of plant and buildings, and interest on debentures, there remains a balance of £14,235 6s. 1d. It is proposed to apply £625 to reduction of preliminary expenses, £500 to reduction of provisional orders account, and £3,000 to reduction of property, patents and goodwill account, to meet depreciation under these heads. The net balance of £10,426 19s. 3d. is available for dividends. An interim dividend, absorbing £3,808 6s. 10d. has already been paid upon the preference shares for the six months from 10th August to 10th February last, and it is proposed to apply £3,505 4s. 6d. to the payment of a further dividend upon these shares, making up the full preferential dividend at the rate of 6 per cent. per annum from the date of registration of company to 30th June, 1890. The directors recommend that the balance of £2,796 14s. 9d. be carried forward to next account.

The temporary interruption to business caused by the amalgamations with other companies and extensions of works has to some extent adversely affected the profit and loss account, and as several months had necessarily to elapse before the new works at Loughborough could be completed, the advantages of the lower cost of production at the country works were not obtained in regard to a large proportion of the orders executed. In view of all these circumstances, the directors consider the result of the year's working as encouraging.

The Falcon works at Loughborough have been considerably enlarged during the year at an expenditure of about £20,000, and the extension of these works enables the company to manufacture at a materially reduced cost engines, boilers, cars, and electrical machinery of practically every description and size. The directors are of opinion that this money has been well spent, and they anticipate good results in the future from the erection of these works.

It affords the directors much satisfaction to state that the Bill confirming the provisional order for lighting the central division of the City of London has been passed by Parliament. The agreement with the Commissioners of Sewers of the City of London provides that the work for the purpose of public lighting shall be commenced within nine months from the 21st May last, and the directors are making the necessary preparations for giving effect to this condition.

The company has also obtained a provisional order for Bournemouth, where a central electric light station has already been erected, which promises to yield very satisfactory returns. The directors have applied to the Board of Trade for provisional orders for several other towns in the United Kingdom where the company has interests to protect.

The Austro-Hungarian businesses have developed in a satisfactory manner, and the Vienna factory shows improving results, both as to volume of trade and as to net profit. The necessity for providing additional factory accommodation in Vienna has now arisen, and the directors are concluding negotiations for the acquisition of some freehold land and buildings adjoining the present works. They have also under consideration proposals for a re-arrangement of the company's interests in the Vienna business.

The directors have, with the assistance of Captain Rowan, the late general manager of the Australasian Company, fully examined into the character of the business acquired from that company, and have made arrangements for the proper development of the company's valuable patents and organisation in the Colonies.

### West Coast of America Telegraph Company.

A MEETING of shareholders was held at Winchester House, on Monday, the 1st inst., at 1 o'clock. The proceedings were strictly of a private nature, and representatives of the press were excluded. We understand that the chairman (Mr. A. Marshall) made a statement as to the position and prospect of the company which was regarded as somewhat reassuring. A short discussion, quiet in character, followed, and the meeting broke up without any resolution being passed.

The following letter appeared on Saturday:—

To the Editor of THE FINANCIAL NEWS.

"Sir,—I beg to enclose a printed notice issued by the directors of this company, whose shares, at the beginning of this year, were quoted at 11½, while they are now scarcely saleable at 3½. This excessive depreciation in value is said to be due to threatened competition; but the eagerness of the shareholders to part with their holdings is, in my opinion, mainly owing to the want of confidence in the management of the company.

"The directors—three in number—take in fees no less a sum than £1,475 per annum. Their business capacity may be judged from the accompanying notice convening a meeting on Monday next, without mentioning the hour at which the shareholders are to attend. From the notice, it would appear as if the shareholders were expected to pass the whole day at 50, Old Broad Street, discussing the company's affairs.

"As the company paid a dividend of 6 per cent. last year, and added £25,000 to the reserve fund, a sum equal to 8 per cent. on the capital, I thought that the shares were worth a small premium, and unfortunately became a purchaser at 10½. I ought, before buying, to have inquired into the administrative ability of the directors, who have succeeded in bringing down the price of the shares some 70 per cent. The published traffics of the company show little or no decrease over the earnings of last year.

"Living in Devonshire, I cannot attend the meeting on Monday next, but I hope that the London shareholders will assemble in force and insist on some reform of the present board of directors.

"I am, sir, yours, &c.,

"A COUNTRY SHAREHOLDER."

**Hartlepool Gas and Water Company.**—At the annual general meeting of the company held recently at Hartlepool, Mr. W. H. Fisher, the chairman, after congratulating the shareholders on a prosperous year, and prognosticating the sustained activity of trade in the district for another year, observed as to the future, that the cost of production of gas would be increased by fully £3,000 in coal, and the necessity of raising the price by 2d. per 1,000 feet had been seriously discussed, but abandoned for the present, in the hope that the increased cost would be partially met by increased consumption—otherwise, the question must be shortly reconsidered.

**The Bankers and Merchants' Telegraph Company.**—The property and franchises of the company have been sold at auction under foreclosure. Colonel Robert G. Ingersoll bid it in for \$390,000.

**The Brush Electrical Engineering Company, Limited.**—The transfer books will be closed to the 9th inst., inclusive.

## TRAFFIC RECEIPTS.

The Cuba Submarine Telegraph Company, Limited. The receipts for the month of August were £2,900, as compared with £2,815 in the corresponding month of last year. The receipts for the month of May, estimated at £3,400, realised £3,409.

The Direct Spanish Telegraph Company, Limited. The estimated receipts for the month of August were £2,073, against £1,624 in the corresponding period of last year.

The Eastern Extension, Australasia and China Telegraph Company, Limited. The receipts for the month of August, 1890, amounted to £46,526, as against £39,489 in the corresponding period, an increase of £7,037.

The Eastern Telegraph Company, Limited. The receipts for the month of August were £32,606, as against £32,012 for the same period of 1889, or an increase of £594.

West India and Panama Telegraph Company, Limited. The estimated traffic receipts for the half month ended the 31st August are £2,420 as against £2,161, an increase of £259 as compared with the corresponding period.

The Western and Brazilian Telegraph Company, Limited. The receipts for the week ending August 29th, after deducting the fifth of the gross receipts payable to the London Platino-Brazilian Telegraph Company, Limited, were £3,772.

The West Coast of America Telegraph Company, Limited. The gross earnings for the month of August, 1890, were £4,960.

## SHARE LIST OF ELECTRICAL COMPANIES.

Present Amount Issued.	Name.	Stock or Share.	Closing Quotation. (August 28).	Closing Quotation. (September 4.)	Business done during week ending September 4, 1890.

## THE ANNEALING OF COPPER.\*

By G. WYCKOFF CUMMINS, New York.

COPPER is at present almost universally annealed in muffles, in which it is raised to the desired temperature and subsequently allowed to cool either in the air or in water. It may be stated, for the benefit of those not versed in the practical work of annealing, that a muffle is nothing more nor less than a reverberatory furnace. It is necessary to watch the copper carefully, so that when it has reached the right temperature it may be drawn from the muffle and allowed to cool. This is extremely important, for it is found that if the copper is heated to too high a temperature, or is left in the muffle at the ordinary temperature of annealing for too long a time, it is "burnt," as the workmen say. Copper that has been "burnt" is yellow, coarsely granular, and exceedingly brittle—so much so that in some samples in my possession it cannot be bent once at a right angle without breaking. It is even more brittle at a red heat than when cold.

In the case of coarse wire it is found that only the surface is "burnt," while the interior is damaged to a far less extent. This causes the exterior to split loose from the interior when bent or when rolled, thus giving the appearance of a brittle copper tube with a copper wire snugly fitted into it. Cracks a half-inch in depth have been observed on the surface of an ingot on its first pass through the rolls, all due to this exterior "burning." It is quite apparent that copper that has been thus overheated in the muffle is entirely unfit for rolling, either for rods or sheet copper or for wire drawing. It is found that the purer forms of copper are far less liable to be harmed by overheating than samples containing even a small amount of impurities. Even the ordinary heating in a muffle will often suffice to "burn" in this manner the surface of some specimens of copper, and thus render them entirely unfit for further working. The explanation of this will be made later. Copper that has been thus ruined is of use only to be refined again.

As may be inferred from the above, only the highest grades of refined copper are at present used for drawing or for rolling. This is not because the lower grades, when refined, cannot stand sufficiently high tests, but because the present methods of working are not adequate to prevent these grades of copper from experiencing the deterioration due to overheating. This is unfortunate for the manufacturer since, I understand, he has to pay cash in advance for the highest grades of refined copper.

In order better to appreciate the explanation of the various phenomena of copper annealing, let us see what refined copper is. The process of refining copper consists in an oxidising action followed by a reducing action which, since it is performed by the aid of gases generated by stirring the melted copper with a pole, is called poling. The object of the oxidation is to oxidise and either volatilise or turn to slag all the impurities contained in the copper. This procedure is materially aided by the fact that the suboxide of copper is freely soluble in metallic copper, and thus penetrates to all parts of the copper, and, parting with its oxygen, oxidises the impurities. The object of the reducing part of the refining process is to change the excess of the suboxide of copper to metallic copper. Copper containing even less than 1 per cent. of the suboxide of copper shows decreased malleability and ductility, and is both cold short and red short. If the copper to be refined contains any impurities, such as arsenic or antimony, it is well not to remove too much of the oxygen in the refining process. If this is done, "overpoled" copper is produced. In this condition it is brittle, granular, of a shiny yellow colour, and more red short than cold short. When the refining has been properly done, and neither too much nor too little oxygen is present, the copper is in the condition of "tough pitch," and is in a fit state to be worked.

"Copper is said to be tough pitch when it requires

frequent bendings to break it, and when, after it is broken, the colour is pale red, the fracture has a silky luster, and is fibrous, like a tuft of silk." On hammering a piece to a thin plate it should show no cracks at the edge. At tough pitch copper offers the highest degree of malleability and ductility of which a given specimen is capable. This is the condition in which refined copper occurs in the market, and if it could be worked without changing this tough pitch any specimen of copper that could be brought to this condition would be suitable for rolling or drawing. We have seen that tough pitch is changed if we either add oxygen to or take oxygen from refined copper.

By far the more important of these is the removal of oxygen, especially from those specimens that contain more than a mere trace of impurities. This is shown by the absolutely worthless condition of overpoled copper. The addition of carbon also plays a very important part in the production of overpoled copper.

That the addition of oxygen to refined copper is not so damaging is shown by the fact that at present nearly all the copper that is worked is considerably oxidised at some stage of the process, and not especially to its detriment.

Let us see how the above facts are related to the process of annealing copper. I have already referred to what is known as "burnt copper." This you may already have recognised as nothing more nor less than copper in the overpoled condition. This is brought about by the action of reducing gases in the muffle. By this means the small amount of oxygen necessary to give the copper its tough pitch is removed. You must remember that this oxygen is combined with impurities in the copper, and thus renders them inert. For example, as explained by Dr. Peters, the oxide of arsenic or antimony is incapable of combining more than mechanically with the copper, but when its oxygen is removed, the arsenic or antimony is left free to combine with the copper. This forms a very brittle alloy, and one that corresponds almost exactly in its properties to overpoled copper. To be sure, overpoled copper is supposed to contain carbon, but that this is not the essential ruining principle in case of annealing is shown by the fact that pure copper does not undergo this change under conditions that ruin impure copper, and also by the fact that the same state may be produced by annealing in pure hydrogen, and thus removing the oxygen that renders the arsenic or antimony inert. No attempt is made to deny the well known fact that carbon does combine with copper to the extent of 0.2 per cent., and cause it to become exceedingly brittle. It is simply claimed that this is probably not what occurs in the production of so-called burnt copper during annealing. The amount of impurities capable of rendering copper easily "burnt" is exceedingly small. This may be better appreciated when it is considered that from 0.01 to 0.2 per cent. expresses the amount of oxygen necessary to render the impurities inert. The removal of this very small amount of oxygen, which is often so small as to be almost within the limits of the errors of analysis, will suffice to render copper overpoled, and ruin it for any use.

Perhaps the most interesting part of this article, to practical men at least, will be the description of a method of avoiding the numerous accidents that may occur in the annealing of copper, due to a change of pitch. As already pointed out, the quality of refined copper is lowered if oxygen be either added to or taken from it. It is quite apparent, therefore, that a really good method of annealing copper will prevent any change in the state of oxidation. To accomplish this it is necessary to prevent access to the heated copper both of atmospheric air, which would oxidise it, and of the reducing gases used in heating the muffle, which would take oxygen away from it. Obviously the only way of accomplishing this is to enclose the copper when heated and till cool in an atmosphere that can neither oxidise nor deoxidise copper. I find that by so doing copper may be heated to the melting point and allowed to cool again without suffering at all as regards its pitch. There are comparatively few gases that can be

\* *Scientific American.*

used for this purpose, but, fortunately, one which is exceedingly cheap and universally prevalent fulfills all requirements, viz., steam. In order to apply, then, in practice, the principles already enunciated, it is necessary only to anneal copper in the ordinary annealing pots, such as are used for iron; care being taken to enclose the copper while heating and while cooling in an atmosphere of steam. This will effectually exclude air and prevent the ingress of gases used in heating the annealer. Twenty-four hours may be used in the process, as in the annealing of iron wire, with no detriment to the wire. This may seem incredible to those manufacturers who have tried to anneal copper wire after the manner of annealing iron wire. By this method perfectly bright annealed wire may be produced. Such a process of annealing copper offers many advantages. It allows one to use a grade of copper that has hitherto been worked only at a great disadvantage, owing to the ease with which it gets out of pitch. It allows one to use annealers such as are ordinarily used for annealing iron, and thus cheapens the annealing considerably as compared with the present universal use of muffles. There is no chance of producing the overpoled condition from the action of reducing gases used in heating the muffles. There is no chance of producing the underpoled condition due to the absorption of suboxide of copper. None of the metal is lost as scale, and the saving that is thus effected amounts to a considerable percentage of the total value of the copper. The expense and time of cleaning are wholly saved. Incidentally bright annealed copper is produced by a process which is applicable to copper of any shape, size, or condition, a product that has hitherto been obtained only by processes (mostly secret) which are too cumbersome and too expensive for extensive use and, as is the case with at least one process with which the author is acquainted, with the danger of producing the over-

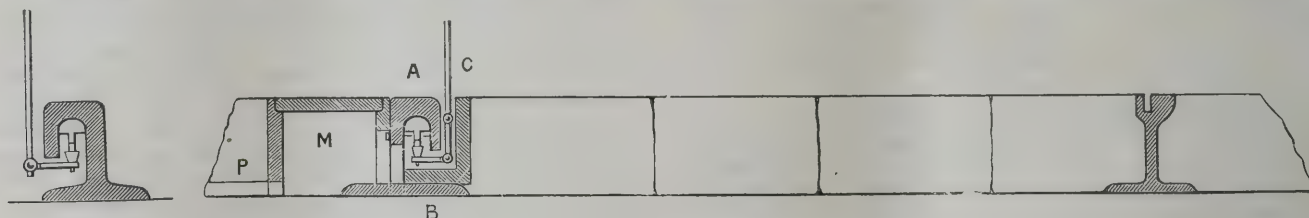

FIG. 2.

poled condition, often in only a small section of the wire, but thus ruining the whole piece.

If it is desired, the copper may be annealed in an apparatus so arranged that the copper when heated may be dropped into a body of water without access of air, and thus make a far smaller annealing plant suffice. It may be mentioned that copper seems to be made neither softer nor harder by being cooled suddenly in this manner than if cooled slowly, though some of the alloys of copper are rendered somewhat softer by a sudden cooling; in fact, there is not the slightest evidence anywhere to justify the quite prevalent belief that an art of hardening copper was known to the ancients. The hardest tools of the ancients were made of bronze, not copper.

By application of the same principles it is possible to prevent both deoxidation and oxidation in the heating of copper ingots for the rolls, and thus, by keeping copper at tough pitch all along, any copper that can be given tough pitch can be used for rolling as sheet copper or for wire.

I think it also practicable to produce bright copper rods direct from the rolls.

### PEDDIE'S CONDUIT RAIL.

THIS conduit rail is for use on tramways and railways worked by electricity. The conductor, properly insulated, is placed within the rail, thus avoiding the expense and inconvenience of a separate central conduit,

and the brush is applied to the underside. The wooden T-insulator (which is further itself insulated from the rail) is secured to the rail by a wooden dowell. The horizontal copper conductor is attached to the insulator by a kneed bracket, screwed to the insulator, the conductor being recessed so as to give a flush surface for the brush to travel over. Provision is made for points and crossings, and also for preventing the brush, &c., coming in contact with the rail. The slot in the rail answers both for wheel flange and also for the vertical conductor to the motor on the car. At suitable distances small iron cases, termed "mud traps," are placed opposite holes in the side of the rail. These permit of the rail being easily cleaned, and also of the renewal of the conductor without the permanent way being lifted. The rail can be flushed with water, and thus easily and effectively cleaned without affecting the conductor. It can also be easily applied to existing horse tramways.

The figs. show a cross section. A is the rail, with the conductor within it. C is the bracket (pendant from the car with motor) carrying the brush, which is applied to the underside of the conductor. M is the "mud trap" with movable cover, and pipe, P, to gutter. These pipes need only be at requisite distances, not at every "mud trap." Fig. 2 shows the arrangement for railways. In this case, the brush is applied from the outside instead of from the inside of the rail. The reason of this is, that in the case of railways, the pressure will be much greater than in the case of tramways. It is therefore desirable to have the body of the rail directly under the tread of wheel.

The object of the conduit rail is to provide a *simple, safe, and efficient* method of working electric tramways and railways, *at the least possible expense*, avoiding all the inconvenience and expense of costly central conduits, or poles and other overhead apparatus, for the

FIG. 1.

conductors. The following points have also been borne in mind:—

1. Placing the conductor where it will be safe from injury both to itself and the public.

2. Making provision for easily cleaning and flushing the rail without affecting the conductor within it. This is secured by means of the "mud traps," which at suitable points have pipes to the gutters.

3. Making provision for easily renewing the conductor when it is worn, without lifting permanent way. Thus, by removing the covers of the "mud traps," the brackets which hold the conductor to the T-insulator can be unscrewed, the conductor lowered, and then raised and removed through the slot. A new conductor can then be lowered and fixed in a similar manner. The T-insulators can also be removed and renewed by means of the "mud traps."

4. Making the rail suit for ordinary horse or steam or compressed air, or accumulator cars. As far as these cars are concerned, the "conduit rail" is practically an ordinary slot rail.

5. Avoiding any central slot rail (between the wheel rails), which is a great inconvenience to ordinary street traffic.

6. Making the system such that it can be easily and effectively, and without great cost, applied to existing tramways. This is done by simply lifting one of the ordinary slot rails and replacing it with a conduit rail with conductor. By doing this on short sections at night, all interruption of ordinary or car traffic is avoided.

7. General simplicity and freedom from liability to derangement.

**ELECTRICALLY-OPERATED TREVELYAN INSTRUMENTS WITH CARBON "ROCKERS" AND "BEARERS."**

By A. M. TANNER.

EVERYTHING concerning the genesis of the microphone and carbon telephone should be presented to the scientific and technical world, so that hereafter there shall be no further misconception as to the actual discoveries made by Prof. Hughes and Mr. Edison; the former having used hard carbon contacts in his microphone, and the latter having resorted to compressible, or soft carbon, in his original carbon telephone.

I have already shown, in an article which appeared in the *ELECTRICAL REVIEW* of August 22nd, that as far back as the year 1858 Rollman drew attention to the fact that a hard carbon prism resting loosely upon carbon bearer points included in a closed electric circuit will, by its vibratory movement produced by the passage of the electric current, serve to vary the points or surfaces of contact, and thus effect a change of tension of the electric current flowing in the circuit.

I now wish to call attention to another electrically-operated Trevelyan instrument, which has a carbon rocker vibrating upon carbon bearers.

In the London, Edinburgh, and Dublin *Philosophical Magazine* for 1859, Fourth Series, Vol. XVII., page 358, is an article by Prof. J. D. Forbes, of the University of Edinburgh, entitled, "Notes on Certain Vibrations Produced by Electricity." After reviewing prior experiments of Prof. Gore with a Trevelyan instrument having a hollow copper sphere, made to run on a circular track by the action of electricity. Prof. Forbes continues as follows, viz. :—

"I have obtained very active vibrations of carbon (such as is used in one of the elements of Bunsen's battery) resting upon brass, and also when it rests upon two pieces of carbon connected with the terminals of a battery. For this purpose, a battery having a certain amount of intensity is requisite, in order to overcome the resistance of carbon as a conductor, but the vibrations are most energetic. The extremely small expansion which takes place in carbon by heat is another argument against that view of the Trevelyan experiment."

The above-quoted description is not accompanied by an illustration, but from collateral evidence it undoubtedly warrants the sketch given below of the the arrangement of bearers and rocker.

It will readily be perceived how closely this resembles the "three-nail microphone of Prof. Hughes. I think it will be conceded that, in view of the instruments constructed by Rollman, Paalzow, and Forbes, the novelty of the microphone must be sought in the method of varying the force of an electric current by the action of sonorous vibrations; in other words, it appears almost impossible to uphold a claim for a microphone instrument in which a carbon electrode rests loosely upon another electrode, for the purpose of varying the tension of the current in a closed electric circuit in which said electrodes are included.

I believe it has been held by an English Court that "the circumambient air" is the equivalent of a diaphragm in a telephone, having a current tension regulator of carbon. If this is true, then the instruments of Rollman, Paalzow, and Forbes must have an exceedingly close bearing upon a microphone or carbon telephone whose novelty rests solely upon a variable contact rheostat of carbon, introduced into a closed

electric circuit. When it comes to the principle or method of operating the carbon rheostat by sonorous vibrations, then the Trevelyan instruments considered in my articles lose their pertinency. They can only be used to show that the device employed in a microphone (without a diaphragm) are old in other instruments, and that the action of a variable contact rheostat made of hard carbon, for changing the tension of the current in a closed electric circuit was discovered by Rollman.

**KEMMLER'S EXECUTION AS SEEN BY AN ELECTRICIAN.**

By CHARLES R. HUNTLEY.

IT is with pleasure that I comply with the request of the *Electrical World* to give my observations on the Kemmler electrocution. One of the prime reasons which prompted me to attend this event was that the electrical fraternity would have the benefit, so far as I was able to observe, of what occurred at this electrocution.

The dynamo, as is well known, is one of the Westinghouse type, the exciter being of the usual pattern sent with all dynamos of this make. It was located in the second story of the east wing of the prison, about 1,000 feet from the room wherein the death chair was located. The power was supplied by a 45 H.P. engine, belted to a 2-inch shaft, which ran through the dynamo room. On this shaft were a 36-inch pulley and a 30-inch pulley. From the 36-inch pulley was run an 8-inch belt down to a 12-inch pulley on the dynamo, and a 6-inch belt ran from the shaft to the exciter. No voltmeter or ammeter was connected up in circuit at this point. A resistance box was placed at the end, over the exciter. The wires led out through the window up over the roof on porcelain and glass insulators, down across and around the dome of the front of the prison; from there down on the wall into the window of what was known as the original room for the electrocution. This wire was of No. 12 B. and S. gauge, rubber covered, and said to have been made by the Edison Company. On the switchboards were two Cardew voltmeters, both connected up with resistance coils. Both were connected with switches, and between the two was a lamp board, which, I am told, is of the usual type used in the Edison stations. In this were 20 100-volt lamps of Edison make, and an ammeter of Bergman & Co.'s make was a part of the lower portion of the board.

There were two jaw switches—one known as the fatal switch and the other as the lamp board switch—which were placed on the wall of easy access to the executioner. From the board there ran wires of the same gauge into the chair, one being fastened to the electrode on the bottom, and the other to the electrode on the top. This is all of the electrical apparatus and distribution that I noted. A Mr. Davis was the man in charge. I might say that my curiosity prompted me to go with him to witness the first test of the machinery on Tuesday afternoon. Mr. Davis adjusted the brushes on both dynamo and exciter, and then left the apparatus in charge of three convicts who were assistants.

After going back to the switchboard signals were given to start up the dynamo. At that time the voltmeter showed about 1,000 volts. The lamps were in circuit and were about two-thirds candle-power. Again, in the evening, all of the witnesses summoned by law, together with the doctors and professional men, witnessed another test, which was substantially the same as that of the afternoon. There was no record taken of what the voltage was at that time, but an assumption was made that it was from 1,000 to 1,200 volts.

The morning of the execution came, and those who were to witness the first experiment upon human life by the electric current found, in a dimly lighted room,

the death chair, and around about the walls in a circle seats for their accommodation. I do not know that it will be of any interest to your electrical readers to record here (inasmuch as the Press has given all of that) what took place with reference to the in-coming of Kemmler and his spiritual advisers, but suffice to say that the man who stood before us exhibited the most unconcern of any of the 23 men who were within the room. After being strapped and pinioned to the chair, Kemmler assisting, and to quite an extent, the electrodes at the head and back were securely placed, the strap securely fastened over his face by the warden, the word was given to the three men who were in the room behind a closed door, and we witnessed the effect of the first contact by a contraction, or rather drawing up of his whole body within his bonds. The time by actual count was 17 seconds. The current then, by direction of Dr. Spitzka, was turned off, and to all appearances Kemmler was dead. As the doctor said: "There are unmistakable evidences of death about his nose, and I have never known such a condition as is demonstrated on this man except in death." One of the attendants then removed the electrode from his head, and those who were advocates of the killing by electricity were elated beyond expression. The look of entire satisfaction which spread over the countenances of some of the learned doctors was an indication of the joy that their labours had brought them in the death of Kemmler, apparently so painless and still. The next sound that was heard was of Dr. Spitzka saying: "This man is not dead. Turn on the current." The electrode, in a hurried manner, was again applied to his head, and the signals were sent out by one of the attendants in the room to start up the machinery. This was done. How soon I cannot say. The laymen were all in confusion at the horrible sounds that were coming from the man who had been pronounced dead. Words fail me with which to give you the faintest idea of what these were. There were men in that room who had witnessed executions and had seen death in various forms, but each and every one of them was horror stricken at this sudden change in the condition of the culprit. Various reports have been made as to the length of time of the second contact, but it has been my privilege to be associated somewhat with the gentleman who was in the dynamo room while the machine was in operation. He tells me that after the first shock the signals were given to shut down. This was done by the convicts. Then a short space—perhaps two minutes—and the signal was given to start again. Instantly another signal was given for more speed, and so on, until the dynamo was running, and as he stated, it was fairly jumping from the floor. I forgot to mention that during the time of the second shock the circuit was made and broken three times. At each of these periods the dynamo would be nearly stopped, and the belt after the first shock was nearly thrown off the dynamo pulley. Then a convict was instructed to hold the belt on each side of the pulley, which was done during the time that the dynamo was running, which was about three and a half minutes. Added to the horror of the sounds emitted by the so-called dead man, were what the doctors said were convulsions, but whatever it may be called, convulsions or not, I am told by one of the physicians, as reputable as any there, that life did exist in the man, though not sensibility, after the first shock. The electrode at his back had become loosened, admitting of arcing, and at this point of contact the flesh was literally roasted. The stench of burning flesh was almost unbearable to those of us unfamiliar with such things.

What occurred in the lamp room no one will ever know beyond the three persons present. I endeavoured to ascertain what the voltage was, but I did not succeed in getting any information, and I question very much whether Mr. Davis himself, who had charge of the electrical appliances, knows to what voltage Kemmler was exposed at either time.

From an electrical standpoint there was nothing gained to show what amount of current it takes to kill. No data of either the electrical or mechanical apparatus

was taken, and whoever assumes to say what the voltage was that Kemmler received must guess between 800 and 2,000.

#### MR. EDISON ON THE KEMMLER EXECUTION.

Mr. T. A. Edison, when interviewed, said: In December, 1887, I wrote to a man who asked for my views, that I would join heartily in a movement to abolish capital punishment. If it was not to be abolished, however, I said, we should adopt the quickest and least painful method of accomplishing it, and I believed an intermittent dynamo current properly applied would best meet these requirements. I still believe this. In the Kemmler execution, according to the reports printed in the newspapers, the fault rests upon the doctors. They acted upon theory, and knowing the base of the skull to be the nerve centre of the human system, they determined to reach it as directly as possible. Theoretically they were right, but practically they were wrong, as experience has demonstrated. In not a single one of the 30 perfect examples of the power of electricity to produce instant death that have occurred in and around New York was it applied to the head. Of what use has the death of these 30 men been? In every instance the fatal charge entered through the hands. In no case among these accidental deaths was the current that passed through the body one-half what it was announced was to be used on Kemmler. Electricity travels through fluids, and especially through the saline fluids of the body, much more freely than through bone. The hands, when cleansed and immersed in a solution of caustic soda, afford an excellent contact for electric currents, and as the fingers, hands and arms are full of blood, they make a good conductor of electricity. On the other hand, bone is one of the poorest conductors, and by making the points of contact on the thickest part of the skull, and the portion of the spine affording most resistance, the doctors invited a degree of failure. Neither contact could have been made in a less desirable place. The hair of the head is also a non-conductor, and offers resistance to electrical currents. If, as is stated, Kemmler's skin was burned at the points of contact, that proves that he received but a small portion of the charge. Had he received the full 1,300-volt current for the length of time stated, he would have been carbonised or mummified. If the report that 20 incandescent lamps were in the circuit and illuminated at the time the current was applied to Kemmler is true, the explanation is in part at least furnished. These lamps offer resistance to the flow of the current, and 20 of them would greatly reduce the potential of the current. They should have been removed from the circuit.

"How do you account for the muscular and apparently respiratory action after the current had been once turned on?" was asked. "Oh, I have no doubt he was dead," replied Mr. Edison. "I think the doctors will probably agree to that. You know there is often muscular movement after death by hanging. Kemmler was undoubtedly killed at the first, unless some big mistake was made. Undoubtedly all those present were greatly excited. I should have been excited myself at such a time. In that excitement there may have been some bungling. I think, when the next man is placed in the chair to suffer the death penalty, that death will be accomplished instantly and without the scene at Auburn."

**Proposed Electric Tramway at Plymouth.**—Arrangements are in progress for constructing a new tramway at Plymouth, and bringing the old lines, which have been for a considerable period in disuse, once more into working order. The work is to be carried out by Messrs. Grover & Co., and it is said to be the intention of the promoters of the new scheme to apply for the necessary powers to enable them eventually to use electricity as the motive power.

BRITISH ASSOCIATION FOR THE ADVANCE-  
MENT OF SCIENCE.—LEEDS, 1890.

THE sixtieth meeting of the Association opened at Leeds on Wednesday. A good many years have elapsed since the last meeting in this town, during which time the district, from a manufacturing point of view has greatly developed. There will probably not be a great number of electrical papers read at the meeting, but those promised bid fair to rank as valuable additions to technical literature.

On Wednesday evening Sir Frederick A. Abel, C.B., D.C.L., F.R.S., gave the presidential address, an abstract of which follows. Thursday was spent in hearing the addresses of the presidents of the various sections, and it will not be before to-day that they settle fairly down to work.

## ABSTRACT OF ADDRESS\*

BY SIR FREDERICK AUGUSTUS ABEL, C.B., D.C.L.  
(Oxon.), D.Sc. (Cant.), F.R.S., P.P.C.S., Hon.M.Inst.C.E.,  
*President.*

Among the branches of science in the practical applications of which the greatest strides have been made since the Association met at Leeds in 1858, is electricity. That year witnessed the accomplishment of the first great step towards the establishment of electrical communication between Europe and America, by the laying of a telegraph cable connecting Newfoundland with Valencia. Through this cable a message of 31 words was shortly afterwards transmitted in 35 minutes; an achievement which, though exciting great enthusiasm at the time, scarcely afforded promise of the succession of triumphs of ocean telegraphy which have since surpassed the wildest dreams of the pioneers in the realms of applied electricity.

The development of the electric telegraph constitutes a never-failing subject of the liveliest interest. The experiments made by Stephen Gray, in 1727, of transmitting electrical impulses through a wire 700 feet long; by Watson, 20 years afterwards, of transmitting frictional electricity through many thousand feet of wire, supported by a line of poles, on Shooter's Hill, in Kent; and by Franklin, who carried out a similar experiment at Philadelphia—although they were followed by many other interesting and philosophical applications of frictional electricity to the transmission of signals—were not productive of really practical results. The work of Galvani and of Volta was more fruitful of an approach to practical telegraphy in the hands of Sömmering and of Coxe, while the researches of Oersted, of Ampère, of Sturgeon, and of Ohm, and especially the discoveries of volta-electric induction and magneto-electricity by Faraday, paved the way for the development of the electric telegraph as a practical reality by Cooke and Wheatstone in 1837. How remarkable the strides have been in the resources and powers of the telegraphist since that time is demonstrated by a few such facts as these; the first needle instrument of Cooke and Wheatstone transmitted messages at the rate of four words per minute, requiring five wires for that purpose; six messages are now conveyed by one single wire, at ten times that speed, and news is despatched at the rate of 600 words per minute. Duplex working, which more than doubled the transmitting power of a submarine cable, was soon eclipsed by the application of Edison's quadruplex working, which has in its turn been surpassed by the multiplex system, whereby six messages may be sent independently, in either direction, on one wire. When last the British Association met in Leeds, submarine telegraphy had but just started into existence; 30 years later, the accomplished President of the Mechanical Section informed us, at our meeting at Bath, that 110,000 miles of cable had been laid by British ships, and that a fleet of nearly forty ships was occupied in various oceans in maintaining different cables and laying new ones.

The important practical achievements by which most formidable difficulties have been surmounted, step by step, in the successive attainment of the marvellous results of our day, have exerted an influence upon the advancement, not merely of electrical science, but also of science generally and of its applications, fully equal to that which they have exercised upon the development of commerce and of the intercourse between the nations of the earth.

Thus the laying of the earliest submarine cables between 1851 and 1855, led Sir W. Thomson, in conference with Sir George Stokes, to work out the theory of signalling in such cables, by utilising the mathematical results arrived at by Fourier in his investigation of the propagation of heat waves. The failure of the first Atlantic cable led to the survey of the bottom of the Atlantic, which was the forerunner of deep-sea explorations, culminating in the work of the *Challenger* expedition, and opening up new treasures of knowledge scarcely dreamt of when last the British Association met at Leeds. To the difficulties connected with the early attempts at submarine telegraphy, and the determination with which Thomson drove home the lessons learned, we owe the systematic investigations into the causes of the variations in resistance of copper conductors, and the consequent improvements in the metallurgy of copper, which led to the realisation of the high standard of purity of metal essential for the efficient working of telegraphic systems, and also to the extensive utilisation of

electricity in the production of pure copper. The rare combination of originality in powers of research and perspicuity in mathematical reasoning, with inventive and constructive genius, for which Thomson has so long been pre-eminent, has placed at the disposal of the investigator of electric science, and of the practical electrician, instruments of measurement and record which have been of incalculable value, and which owe their origin to the theoretical conclusions arrived at by him in his researches into the conditions to be fulfilled for the attainment of practical success in the construction and employment of submarine cables. The mirror galvanometer, the quadrant electrometer, the syphon-recorder, and the divided ring electrometer, are illustrations of the valuable outcome of Thomson's labours; the combination of the last-named instrument with sliding resistance coils has rendered possible the accurate sub-division of a potential difference into 10,000 equal parts. The general use of condensers in connection with cable signalling, due to Varley's application of them for signalling through submerged cables with induced short waves, was instrumental in establishing the fact that all electrostatic phenomena are simply the result of starting an electric current of known short duration round a closed circuit. The practical application of the Wheatstone bridge led to numerous important mathematical investigations, and induced Clerk Maxwell to devise a new mode of applying determinants to the solution of the complicated electrical problems connected with the networks of conductors. The necessity for the universal recognition of an electrical unit of resistance led to the establishment, in 1860, of the Electrical Standards Committee of the British Association, whose long succession of important annual reports was instrumental in most important developments of theoretical electricity, and, indeed, served to open up the whole science of electrical measurement. Matthiessen's important investigations of the electrical behaviour of metals and their alloys, and the preparation and properties of pure iron, were the outcome of the commercial demand for a practically useful standard of electrical resistance, while Latimer Clark's practical standard of electromotive force, the mercurous sulphate cell, became invaluable to the worker in pure electrical research. The unit of resistance established by the British Association Committee received, in 1866, most important scientific application at the hands of Joule, who, by measuring the rate of development of heat in a wire of known resistance by the passage of a known current, obtained a new value of the mechanical equivalent of heat. This value differed by about 1·3 per cent. from the most accurate results arrived at by his experiments on mechanical friction, a difference which eventually proved to be exactly the error in the British Association unit of resistance; so that the true value of the unit of resistance, or ohm, was determined by Joule 15 years before this result was achieved by electricians. Clerk Maxwell's remarkable electro-magnetic theory of light was put to the test, through the aid of the British Association unit of resistance, by Thomson, in determining the ratio of electro-magnetic unit to the electro-static unit of quantity. Many other most interesting illustrations might be given of the invaluable aid afforded to purely scientific research by the practical results of the development of electrical science, and of the constant co-operation between the science student and the practical worker. No one could, more fitly than the late Sir William Siemens, have maintained, as he did in his admirable address at our meeting in Southampton in 1882, that we owe most of the rapid progress of recent times to the man of science who partly devotes his energies to the solution of practical problems, and to the practitioner who finds relaxation in the prosecution of purely scientific enquiries. Most assuredly both these classes of the world's benefactors may, with equal right, lay claim to rank the name of Siemens among those whom they count most illustrious!

In that highly interesting and valuable address, delivered little more than a year before his sudden untimely removal from among us, the numerous important subjects discussed by him included not a few which he had made peculiarly his own in the wide range embraced by his enviable power of combining scientific research with practical work. Prominent among these were the applications of electric energy to lighting and heating purposes, and to the transmission of power, to the future development of which his personal labours very greatly contributed.

Siemens referred to the passing of the first Electric Lighting Bill, in the year of his presidency, as being designed to facilitate the establishment of electric installations in towns; but the anxiety of the Government of that day to protect the interests of the public through local authorities, led to the assignment of such power to these over the property of lighting companies, that the utilisation of electric lighting was actually delayed for a time by these legislative measures. There can now be no doubt, however, that this delay has really been in the interests of intending suppliers and of users of the electric light, as having afforded time for the further development of practical details, connected with generation and distribution, which was vital to the attainment of a fair measure of initial success. The subsequent important modification of legislation on the subject of electric lighting, together with the practical realisation of comparatively economical methods of distribution, the establishment of fairly equitable arrangements between the public and the lighting companies, and the apportionment, so far as the metropolis is concerned, of distinct areas of operation to different competing companies, have combined to place electric lighting in this country at length upon some approach to a really sound footing, and to give the required impetus to its extensive development. Nine companies either are now, or will very shortly be, actually at work supplying, from central stations, districts of London comprising almost the entire western

\* Only that portion of the Address relating to electrical matters has been abstracted.

and north-western portions of the metropolis. As regards other parts of England, there are already 27 lighting stations actually at work in different towns, besides others in course of establishment, and many more projected. The town of Leeds has not failed to give serious attention to the subject of utilising the electric light, and, although no general scheme has yet been adopted, the electricians who now visit this town will rejoice to see many of its public buildings provided with efficient electric illumination.

While the prediction made by Siemens, eight years ago, that electric lighting must take its place with us as a public illuminant, has thus been already, in a measure, fulfilled, important progress is being continuously made by the practical electrician in developing and perfecting the arrangements for the generation of the supply, its efficient distribution from centres, and its delivery to the consumer in a form in which it can be safely and conveniently dealt with and applied at an outlay which, even now, does not preclude a considerable section of the public from enjoying the decided advantages presented by electric lighting over illumination by coal-gas. Yet our recent progress in this direction, encouraging though it has been, is insignificant as compared with the strides made in the application of electric lighting in the United States, as may be gauged by the fact that, while in America the number of arc lamps in use, in April of this year, was 235,000, and of glow lamps about three millions, there are at present about one-tenth the number of the latter, and one hundredth the number of arc lamps, in operation in England.

In some important directions we may, however, lay claim to rank foremost in the application of the electric light; thus, our large passenger ships and our war ships are provided with efficient electrical illumination; to the active operations of our Navy the electric light has become an indispensable adjunct; and our system of coast defence, by artillery and submarine mines, is equally dependent, for its thorough efficiency, upon the applications of electricity in connection with range-finding, with the arrangement and explosion of mines, and with the important auxiliary in attack and defence, the electric light, which, while so arranged, at the operating stations, as to be protected against destruction by artillery-fire and difficult of detection by the enemy, is available at any moment for affording invaluable information and important assistance and protection.

Other important applications of the electric light, such as its use as a lighthouse illuminant, for the lighting of main roads in coal mines, where its value is being increasingly appreciated, and even for signalling purposes in mid-air, through the agency of captive balloons, are continually affording fresh demonstrations of the value of this particular branch of applied electric science.

At the Electrical Exhibition at Vienna, in 1883, where, not long before the lamented death of Siemens, I had the honour of serving as one of his colleagues in the representation of British interests, the progress which had been made in the construction of electrical measuring instruments since the French Exhibition and the Electrical Congress, two years before, was very considerable. The advance in this direction has been enormous since that time; but although the practical result of Thomson's and of Carlew's important work has been to supply us with trustworthy electrical balances and voltmeters, while efficient instruments have also been made by other well-known practical electricians, we have still to attain results in all respects satisfactory in these indispensable adjuncts to the commercial supply and utilisation of electric energy.

In connection with this important subject the recent completion of the Board of Trade standardising laboratory, established for the purposes of arriving at and maintaining the true values of electrical units, and of securing accuracy and uniformity in the manufacture of instruments supplied by the trade for electrical measurements, may be referred to with much satisfaction as a practical illustration of official recognition of the firm root which the domestic and industrial utilisation of electric energy has taken in this country.

The achievements of the telephone were referred to by Siemens in glowing terms eight years ago; but the results then attained were but indications of the direction in which telephonic intercommunication was destined speedily to become one of the most indispensable of present applications of electricity to the purposes of daily life. Preece, in speaking at Bath, two years ago, of the advances made in applied electricity, showed that the impediments to telephonic communication between great distances had been entirely overcome; and now, although considerably behind America and France in the use of the telephone, we are rapidly placing ourselves upon speaking terms with our friends throughout the United Kingdom. The operations of the National Telephone Company well illustrate our progress in telephonic intercommunication: that company has now 22,743 exchange lines, besides nearly 5,000 private lines, its exchanges number 272, and its call-offices 526. The number of instruments under rental in England has now reached 99,000; but, important as this figure is compared to our use of the telephone a very few years ago, it sinks into insignificance by the side of the number of instruments under rental in America, which at the beginning of the present year had reached 222,430, being an increase of 16,675 over the number in 1889. Only thirteen years have elapsed since the telephone was first exhibited as a practically workable apparatus to members of the British Association at the Plymouth meeting, and the number of instruments now at work throughout the world may be estimated as considerably exceeding a million.

The successful transmission of the electric current, and the

power of control now exercised over the character which electrically transmitted energy is made to assume, are not alone illustrated by the efficiency of the arrangements already developed for the supply of the electric light from central stations. Siemens dwelt upon this subject at Southampton with the ardent interest of one who had made its development one of the objects of his energetic labours in later years, and also with a prophet's prognostications of its future importance. In speaking of the electric current as having entered the lists in competition with compressed air, the hydraulic accumulator, and the quick running rope driven by water-power, Siemens pointed out that no further loss of power was involved in the transformation of electrical into mechanical energy than is due to friction, and to the heating of the conducting wires by the resistance they oppose, and showed that this loss, calculated upon data arrived at by Dr. John Hopkinson and by himself, amounted at the outside to 38 per cent. of the total energy. Subsequent careful researches by the Brothers Hopkinson have demonstrated that the actual loss is now much less than it was computed at in 1885; as much as 87 per cent. of the total energy transmitted being realisable at a distance, provided there be no loss in the connecting leads used.

The Paris Electric Exhibition of 1881 already afforded interesting illustrations of the performance of a variety of work by power electrically transmitted, including a short line of railway constructed by the firm of Siemens, which was a further development of the successful result already attained in Berlin by Werner Siemens in the same direction, and was, in its turn, surpassed by the considerably longer line worked by Messrs. Siemens at the Vienna Exhibition two years later. Various short lines which have since then been established by the firm of Siemens are well known, and one of the latest public acts in the valuable life of Siemens was to assist at the opening of the electric tramway at Portrush, in the installation of which he took an active part, and where the idea, so firmly rooted in his mind from the date of his visit to the Falls of Niagara, in 1876, of utilising water-power for electrical transmission—a result first achieved on a small scale by Lord Armstrong—was more practically realised than had yet been the case. Since that time Ireland has witnessed a further application of electricity to traction purposes, and of water-power to the provision of the required energy, in the working of the Bessbrook and Newry tramway, while London at length possesses an electric railway, three miles in length, to be very shortly opened, which will connect the City with one of the southern suburbs through a tram subway, and, although including many sharp curves and steep gradients, will be capable of conveying one hundred passengers at a time, at speeds varying from thirteen to twenty-four miles per hour. During the past year a regular service of tramcars has been successfully worked, through the agency of secondary batteries, upon part of one of the large tramways of North London, with results which bid fair to lead to an extensive development of this system of working. The application of electricity to traction purposes has, however, received far more important development in the United States; at the commencement of this year there were in operation in different States 200 electrical tramroads, chiefly worked upon the Thomson-Houston and the Sprague systems, and having a collective length of 1,641 miles, with 2,346 motor-cars travelling thereon. Further extensions are being rapidly made: thus, one company alone has 39 additional roads, of a collective length of 355 miles, under construction, to be worked through the agency of storage-batteries.

The idea cherished by Siemens, and enlarged upon by him in more than one interesting address, of utilising the power of Niagara, appears about to be realised, at any rate in part; as a large tract of land has been recently acquired, by a powerful American association, about a mile distant from the Falls, with a view to the erection of mills for utilising the power, which it is also proposed to transmit to distant towns; and an International Commission, with Sir William Thomson at its head, and with Mascart, Turrettini, Coleman Sellers, and Unwin as members, will carefully consider the problems involved in the execution of this grand scheme.

The application of electric traction to water-traffic, first successfully demonstrated in 1883, is receiving gradual development, as illustrated by the considerable number of pleasure-boats which may now be seen on the Upper Thames during the boating season, and in connection with which Professor George Forbes proposed, at our meeting last year, that stations for charging the requisite cells, through the agency of water-power, should be established at the many weirs along the river, so as to provide convenient electric coaling-stations for the river pleasure-fleet.

Electrically-transmitted energy was first applied in Germany to haulage work in mines by the firm of Siemens some years ago, and great progress has since been achieved herein on the Continent and in America. Comparatively little has been accomplished in this direction in England; but it is very interesting to note, on the present occasion, that the first successful practical application of electricity in this country to pumping and underground haulage-work was made in 1887, in this neighbourhood, at the St. John's Colliery, at Normanton, where an extensive installation, carried out by Mr. Immisch, so well known in connection with electric launches, is furnishing very satisfactory results in point of economy and efficiency. The gigantic installations existing for the same purposes in Nevada and California afford remarkable illustrations of the work to be accomplished in the future by electrically-transmitted energy.

Among the many subjects of importance studied by Joule with the originality and thoroughness characteristic of his work, was the application of voltaic electricity to the welding and fusion of

metals. Thirty-four years ago he published a most suggestive paper on the subject, in which, after dealing with the difficulties attending the operation of welding, and of the interference of films of oxide, formed upon the highly heated iron surfaces, with the production of perfect welds either under the hammer or by the methods of pressure (of which he then predicted the application to large masses of forged iron), he refers to the possibility of applying the calorific agency of the electric current to the welding of metals, and describes an operation witnessed by him in the laboratory of his fellow-labourer, Thomson, of fusing together a bundle of iron wires by transmitting through them, when imbedded in charcoal, a powerful voltaic current. Joule afterwards succeeded in fusing together a number of iron wires with the current of a Daniell battery, and of welding together wires of brass and steel, platinum and iron, &c. In discussing the question of the amount of zinc consumed in a battery for raising a given amount of iron to the temperature of fusion, he points out that the same object would probably be more economically attained by the use of a magneto-electric machine, which would allow the heat to be provided by the expenditure of mechanical force, developed in the first instance by the expenditure of heat; and he indicates the possibility of arranging machinery to produce electric currents which shall evolve one-tenth of the total heat due to the combustion of the coal used, so that 5,000 grains of coal applied through that agency would suffice for the fusion of one pound of iron. The successful practical realisation of Joule's predictions in regard to the application of electric currents, thus developed, to the welding of iron and steel, and to analogous operations, through the agency of the efficient machines devised by Prof. Elihu Thomson, was demonstrated to the members of the Association by Prof. Ayrton at Bath two years ago, and was shown upon a larger scale to visitors at the Paris Exhibition last year, and recently to highly-interested audiences in London by our late President, Sir Frederick Bramwell. The latter demonstrated that the production of iron welds by means of the Thomson machines was accomplished nearly twice as rapidly as by expert craftsmen; the perfection of the welds being proved by the fact that the strength of bars broken by tensile strains at the welds themselves was about 92 per cent. of the strength of the solid metal. At the Crewe Works, Mr. Webb is successfully applying one of these machines to a variety of welding work. The rapidity with which masses of metal of various dimensions are raised in those machines to welding heat is quite under control; the heat is applied without the advent of any impurities, as from fuel, and the speed of execution of the welding operation reduces to a minimum the time during which the heated surfaces are liable to oxidise. With such practical advantages as these, this system of electric welding bids fair to receive many useful applications.

Another very simple system of electric welding, especially applicable to thin iron and steel sheets, hoops, &c., has been contemporaneously elaborated in Russia by Dr. Bernadov, and is already being extensively used. The required heat at the surfaces to be welded is developed by connecting the metal with the negative pole of the dynamo machine, or of a battery of accumulators, the circuit being completed by applying a carbon electrode to the parts to be heated; the reducing power of the carbon is said to preserve the heated metal surfaces from oxidation during the very brief period of heating. This mode of operation appears to have been practised upon a small scale, some years ago, by Sir William Siemens, to whom we also owe the first attempt to practically apply electric energy to the smelting of metals.

In his address in 1882 he referred to some results attained with his small electrical furnace, and pointed out that, although electric energy could, obviously, not compete economically with the direct combustion of fuel for the production of ordinary degrees of heat, the electric furnace would probably receive advantageous application for the attainment of temperatures exceeding the limits (about 1,800° C.) beyond which combustion was known to proceed very sluggishly. This prediction appears to have been already realised through the important labours of Messrs. Cowles, who some years ago attacked the subject of the application of electricity to the achievement of metallurgic operations with the characteristic vigour and fertility of resource of our Transatlantic brethren. After very promising preliminary experiments, they succeeded, in 1885, at Cleveland, Ohio, in maturing a method of operation for the production of aluminium bronze, ferro-aluminium and silicon-bronze, with results so satisfactory as to lead to the erection of extensive works at Lockport, N.Y., where three dynamo machines, each supplying a current of about 3,000 amperes, are worked by water power, through the agency of turbines, each of 500 H.P., 18 electric furnaces being now in operation for the production of aluminium alloys. These achievements have led to the establishment of similar works in North Staffordshire, where a gigantic dynamo machine has been erected, furnishing a current of 5,000 amperes, with an E.M.F. of 50 to 60 volts. The arrangement of the electrodes in the furnaces, the preparation of the furnace charges (consisting of mixtures of aluminium ore, with charcoal and with the particular granulated metal with which the aluminium is to become alloyed at the moment of its elimination from the ore); the appliances for securing safety in dealing with the current from the huge dynamo machine, and many other details connected with this new system of metallurgic work, possess great interest. Various valuable copper and aluminium alloys are now produced by alloying copper itself with definite proportions of the copper alloy, very rich in aluminium, which is the product of the electric furnace. The rapid production in large quantities of ferro-aluminium—which

presents the aluminium in a form suitable for addition in definite proportions to fluid cast iron and steel—is another useful outcome of the practical development of the electric furnace by Messrs. Cowles.

Great interest attaches to the influence of the metals manganese, chromium, and tungsten upon the physical properties of steel and iron.

The curious effect of manganese in reducing, and even destroying, the magnetic properties of iron was already noticed by Rinnman nearly 120 years ago; one result of Hadfield's important labours has been to place in the hands of such eminent physicists as Thomson, John Hopkinson, and Reinold, materials for the attainment of most interesting information respecting the electrical and other physical characteristics of manganese steel. Hopkinson, from experiments with a sample of steel containing 12 per cent. of manganese, estimated that not more than 9 out of the 86 per cent. of the iron composing the mass was magnetic, and he considered that the manganese enters into that which must, for magnetic purposes, be regarded as the molecule of iron, completely changing its properties, a fact which must have great significance in any theory regarding the nature of magnetisation.

## NEW PATENTS—1890.

12532. "Improvements in electric lighting." S. PITT. (Communicated by Sautter Harlé and Co., France.) Dated August 11. (Complete.)

12628. "Improvements relating to the welding of metals by electricity." H. E. FOWLER. Dated August 12. (Complete.)

12634. "Improvements in dynamo-electric machines or electric motors." T. M. FOOTE. Dated August 12. (Complete.)

12713. "Improvements in electric mains, and in apparatus used in their manufacture." S. Z. DE FERRANTI. Dated August 13.

12819. "Improvements in column type printing instruments operated electrically, for telegraphic and other purposes, and in conductors therefor, which latter also applicable for telephonic and electric transmission generally." S. D. WILLIAMS. Dated August 15.

12827. "Improvements in armatures for dynamo-electric machines." H. J. HILTON. Dated August 15.

12830. "Improvements in secondary batteries, and electrodes therefor." H. H. LAKE. (Communicated by G. A. Johnson and S. L. Holdredge, United States.) Dated August 15. (Complete.)

12832. "An electrical watt meter, also applicable as an ammeter or voltmeter." E. WILSON. Dated August 15.

12874. "Improved electric switch." C. R. BONNE. (Communicated by The Actien Gesellschaft Mix and Genest, Germany.) Dated August 16.

12914. "Improvements in switches for controlling and regulating double or compound electric motors, especially applicable to traction or marine propulsion." A. J. JARMAN. Dated August 18.

12915. "Improvements in brush holders for dynamo-electric motors and generators." A. J. JARMAN. Dated August 18.

12958. "Improvements in apparatus for effecting, by insertion of a coin, the production of electric light for a certain time." D. H. DAVIES and J. M. TOURTEL. Dated August 18.

12997. "An improved electrical rock drill, coal digger, or earth cutter." W. B. BRAIN, A. J. ARNOT, and F. BAKER. Dated August 19. (Complete.)

13002. "Improvements relating to induction coils or transformers chiefly designed for use in welding or otherwise working metal by electricity." H. H. LAKE. (Communicated by E. Thomson, United States.) Dated August 19. (Complete.)

13003. "Improvements in the manufacture of electrodes for primary and secondary batteries." D. PEPPER, jun. Dated August 19. (Complete.)

13006. "Improvements in welding or otherwise working metals by electricity, and in apparatus therefor." H. H. LAKE. (Communicated by E. Thomson, United States.) Dated August 19. (Complete.)

13009. "Improvements in printing telegraphs." J. B. ODELL. Dated August 19. (Complete.)

13013. "Improvements in the manufacture of electrodes for primary and secondary batteries." D. PEPPER, jun. Dated August 19. (Complete.)

13042. "Improvements in or appertaining to electric railway systems." C. J. VAN DEPOELE. Dated August 19. (Complete.)

13044. "A new or improved method and apparatus for effecting economy of electric force in electric writing." P. E. BARDONNAUT and P. JUPPONT. Dated August 19. (Complete.) [Date applied for under Patents Act, 1883, Sec. 103, 20th February, 1890, being date of application in France.]

13049. "Improvements in electric telegraphs, in part applicable for signalling on racecourses and elsewhere." F. E. MACMAHON. Dated August 19.

13129. "Improvements in safety fuses or cut-outs for electric circuits." A. W. SLATER. Dated August 21.

13164. "Improvements in means and apparatus for adjusting electric suspending lights, and for other like purposes." A. LUCAS and E. SUNDBORG. Dated August 21.

13171. "Improvements in fittings for incandescent electric lamps." L. HOEPL and E. COURTIN. Dated August 21.

13175. "Improvements in miners' electric safety lamps." W. PETO. Dated August 21.

13187. "Improvements in electro-motors." R. F. MOORE. Dated August 21. (Complete.)

13190. "Improvements in exciting electro-magnets and electro-magnetic machinery." R. KENNEDY. Dated August 22. (Complete.)

13212. "Improvements in electric accumulators." R. DRYSDALE. Dated August 22.

13233. "Improvements in portable electric lamps, more especially intended for miners' use." THE MINING AND GENERAL ELECTRIC LAMP COMPANY, LIMITED, and W. MOSCROP. Dated August 22. (Complete.)

13276. "Improvements in covering wires to protect them from corrosion, especially applicable to electrical conductors." E. SHIN. Dated August 23.

13282. "Improvements in electric lamps, and means for securing electric lamps in carriages and like vehicles." G. F. SLATTER. Dated August 22. 8d. Claims:—1. Supporting the platinum wires and the filament of an incandescent electric lamp from within the lamp, said support being independent of the usual end support as set forth. 2. The double suspension appliances of an electric incandescent lamp and of its attachments as means for subduing vibrations of the lamp and for preventing oscillation of the filament as set forth. 3. Fixing an India-rubber sheet web and attaching an incandescent electric lamp frame thereto as a means for suspending an electric incandescent lamp in or from a carriage as and for the purposes set forth.

13338. "Improvements in means or devices for use in the distribution of electrical currents." A. W. HEAVISIDE and R. C. JACKSON. Dated September 2. 8d. The objects of the invention are to provide devices which furnish adequate means for localising faults in underground mains, and give protection to the mains and submains from over pressure by means of fuses conveniently situated at the distributing points. The invention also gives great facilities for insulating joints in mains so that the insulation need not be disturbed each time a test has to be made and further also facilities for cross connecting mains so as to make a good main relieve a defective one, or to alter the distribution of electric energy so as to meet varying needs. 10 claims.

14086. "Improved means for effecting the insulation of electrical transformers, switches, switchboards, fuses, commutators, and commutator brushes." W. C. JOHNSON and S. E. PHILLIPS. Dated September 6. 8d. Has mainly for its object to obtain a better insulation of electrical transformers, switches, switchboards, fuses, commutators and their brushes, and it consists in immersing these apparatus in, or surrounding them by, a non-conducting liquid, such as mineral oil, or other suitable liquid whereby they are protected from the atmosphere, and at the same time sparks that may be produced are immediately extinguished, and any tendency to form an arc is greatly lessened. 1 claim.

### ABSTRACTS

#### OF PUBLISHED SPECIFICATIONS, 1889

11032. "Improvements in electric meters." J. OULTON and J. EDMONDSON. Dated July 9. 8d. Consists in the mode of regulating the time of rotation of "torsion balances" in electric meters. The inventors attach the torsion ribbon (by which such balances are suspended) to the stem of a screw, or to a lever by which it is raised or lowered through a curb, such raising or lowering shortens or lengthens the acting portion of the ribbon and thus increases or lessens the speed of rotation as may be required. 7 claims.

11419. "Improvements in electric meters." SIEMENS BROTHERS & Co. (Communicated from abroad by the firm of Siemens and Halske, of Berlin.) Dated July 16. 8d. The apparatus consists essentially of a light arm or lever having a suitably curved face which is caused by clockwork to be turned on its axis at regular intervals of time from a stated rest until it meets the end of a pointer, the position of which is determined by the strength of the current, such angular motion of the arm being transmitted to the wheel work of a counter or registering mechanism. 6 claims.

11425. "Improvements in regulating apparatus for electric arc light lamps." E. FISCHINGER. Dated July 16. 8d. Two electro-magnets are employed, the winding of which magnets is made of fine wire, in derivation from, or parallel to the main circuit, and in combination with these electro-magnets, mechanical devices are employed, by which the armatures of the said electro-magnets will cause the approach of the two carbons for making contact, the separation of the carbons for creating the arc, and the regulation of the position of the two carbons relatively to each other in a quiet and accurate manner. 1 claim.

11519. "Improvements in roses for supporting electric lamps." C. W. FARQUHAR and H. L. DOULTON. Dated July 18. 6d. The inventors make roses for supporting electric lamps in three pieces, A, B, and C. The piece, A, is cemented, screwed or otherwise fixed to the ceiling or wall from which the lamp is to be supported. At the centre it is provided with a projection of a disc like form with a screw thread around its edge. This disc is perforated for the leads to be passed through. The piece B rests against A; it is also perforated to receive the conductors attached to the lamp. The junctions between these and the leads are made between the pieces A and B and are thus concealed. The piece, C, consists of a screw cap which screws on to the piece A, and holds the piece B in position. 2 claims.

11997. "Improvements in electric meters." W. EMMOTT and W. ACKROYD. Dated July 29. 6d. A receiver over the electrodes and dipping into the electrolyte is connected with a closed vessel containing liquid. This closed vessel communicates with the outside by means of a safety tube dipping into the liquid, and is also provided preferably with a syphon. Each time a given amount of gas is liberated by electrolysis, the liquid in the closed vessel is forced up the syphon and also up the safety tube until the bottom of the safety tube is exposed when a quantity of gas is at intervals forced out of the safety tube. The force of this escape is utilised to measure the amount of electricity by means of a mechanical or other suitable device. 2 claims.

13149. "Improvements in apparatus for obtaining reciprocating motion from electric currents, applicable to the operation of electric bells, hammers, caulking tools or the like." T. PARKER. Dated August 20. 6d. The inventor includes in the operating circuit a pair of coils, or their equivalents, by which the hammer, or part to be reciprocated, is moved alternately in opposite directions, the said hammer or part acting upon a switch with scraping or rubbing contacts so arranged that after the reciprocating hammer or moving part is attracted in one direction it causes the switch to make contacts to break the circuit to the coil which attracted the hammer or moving part and complete the circuit through the opposite coil, and so on during the operation of the device. 3 claims.

### CORRESPONDENCE.

#### Cable Testing.

In 1884 I had occasion to use some quick method of finding weak places and bad faults in electric light cables having very heavy conductors, such as strands of 19 No. 6 wires, weighing nearly 12,000 lbs. per mile. My method was as follows:—

Put a drum with a cable coiled on it on an insulated stand, fastening the inside end of the cable to the spindle on which the drum revolves so that there is good rubbing contact, take the outside end to another drum a few feet away also insulated. Now, attach one end of a battery of 300 Leclanché cells to the spindle of the full drum, the other end being "to earth." Having done this, take a man (one peaceably inclined for preference), put a piece of wet cotton-waste in his hand and let him grasp the cable (which must be hauled from the full drum on to the empty one by an insulated man) so that every inch passes through his hand; when the fault comes, if you pick out a nice damp place for the uninsulated man to stand on, he will let you know at once without previous instructions. I had to forego this method owing to a scarcity of the proper sort of men in our locality.

I then tried placing a shunted reflecting galvanometer in the circuit, putting the man on insulators, and this acted perfectly. The especial merit of the above method is, that in the case of a hemp braided cable, such as I was manufacturing then, there is no need to cut the braiding and tapings except at the exact spot where the fault lies; of course the external coverings of the cable must be moderately dry.

Basil Gee,

Late Works Manager and Electrician to  
Callender's Company, Limited.

#### Fusible Cut-Outs in Armatures.

Can any of your readers kindly inform me of any instance where fusible wire has been used in connecting the sections of a gramme armature to the segments of the commutator, the connecting wire acting as a fusible cut-out in case of two segments of the commutator becoming short circuited.

ELECTRICAL HETERODOXY.

THE leading lights in the science of electricity have, in recent years, made notable progress in the field of electrical theory. Faraday first drew attention to the important part played by the dielectric in all electrical phenomena; and his epoch-making discoveries afterwards received their full mathematical interpretation from the genius of Clerk Maxwell. Some of the remarkable results of Maxwell's investigations have received experimental proof by the labours of Hertz and others. Further developments of theory have been made by Thomson, Poynting, Lodge, and others of Maxwell's school.

In science, as in politics, there is a danger that a great leader may prove the evil genius of his followers, and hence the advantage of a little healthy dissent. Mr. James Johnstone, of Edinburgh, is a prominent member of the class who refuse to accept the recent developments of electrical theory. He is no novice in the study of electricity, for he seceded from the orthodox school more than fifty years ago, differing from Faraday on his theory of induction by polarisation of the atoms of the dielectric, and claiming to have converted him by a letter, sent to him in 1839, to the belief that electricity passes through glass by conduction and not by induction. Mr. Johnstone has expounded his views in two pamphlets, one entitled "The Ether Theory of 1839 is the True Theory of the Leyden Jar," and another entitled "Facts which prove that Faraday's Two Force Theory of Electricity is False." We have also had the privilege of seeing Mr. Johnstone's experiments at his laboratory at Dalhousie Terrace, Edinburgh, and some of these are sufficiently remarkable to be of great interest to electricians. Mr. Johnstone's theory of the Leyden jar differs considerably from that which is generally accepted. In his opinion, *induction* is a myth, and electricity will pass by *conduction* through glass of the best insulating quality. He considers that by his experiments he has proved that in charging a

Leyden jar, electricity passes at first by *conduction*, through the glass, "but the moment the electricity begins to pass by *conduction* through the glass, it immediately acts on the particles of the glass, by increasing their attraction, so far that it has the effect of stopping the passage of the current of electricity through the glass to a slight extent, but the current goes on by conduction at a diminished rate until the increased attraction of cohesion of the glass entirely stops the passage of the electricity." In proof of this thesis, Mr. Johnstone offers the following experiments:—A test tube about 8 inches long and 1 inch in diameter, without any extra thickness of glass at the closed end of the tube, or other imperfection, is slipped on the positive electrode of an influence machine, so that the terminal ball reaches close up to, but does not touch the inner end of the tube; and the ball of the negative terminal is brought within a quarter of an inch of the outside bulb of the tube. On turning the machine, sparks are seen to pass from one terminal of the machine to the other, through the substance of the glass, and on examination the tube will be found to be quite free from perforations. This unexpected result can easily be obtained by anyone who chooses to repeat the experiment. In another experiment Mr. Johnstone sends positive sparks into a Leyden jar, supported horizontally on insulating pillars, and having a break in the wire connecting the outer coating to the earth. The direction of the current in the sparks entering the inner coating and leaving the outer coating of the Leyden jar are indicated by insulated gas flames placed in the path of the sparks. It was discovered by Mr. Johnstone in 1839 that these flames are deflected in the direction in which so-called positive electricity is passing. At the commencement of the charging, positive electricity is found to leave the outer coating apparently at the same rate as it enters the inner coating, but at the end of the operation the discharge from the outer coating gradually falls off and finally ceases. If a wire is passed through the stopper of the jar, so that part of the wire passes into the interior of the jar,

while the outer end is pointed and bent at right angles till the point projects over the edge of the jar. Mr. Johnstone finds that as long as positive electricity is passed into the interior of the jar, positive electricity continues to leave the outer coating. This does not stop as in the former case, but may be continued for any length of time.

Now, do these experiments necessarily prove that electricity passes through glass by *conduction*, and that *induction* is a myth? With all respect to Mr. Johnstone, we think not. The experiment with the test tube is a remarkable one, and it will be new to most electricians to see the electrical spark apparently passed through glass without perforating it. We have ourselves repeated the experiment, and we believe that the following explanation is correct. In the case of all the test tubes we have experimented with we have found that even when thoroughly dried they are comparatively good conductors for the electric spark from an influence machine. Hence, in the experiment described above, when the spark from the positive electrode of the influence machine strikes the interior of the test tube, an equal quantity of electricity must leave the outer coating; just as when a billiard ball strikes one of two billiard balls lying in contact the outer ball will be driven off without apparently producing any movement in the ball which was struck. The charge imparted to the inner surface of the test tube is now quickly dissipated by conduction, and the interior of the tube is ready to receive another spark with exactly similar results. In the case of a Leyden jar with glass of good insulating quality the first spark of electricity imparted to the inner coating will cause a similar spark to leave the outer coating, but the second, third, or some succeeding spark will cause a spark to leap from the inner to the outer coating, through the mouth of the jar if the jar is open mouthed. This last result, it appears to us, completely explains the action of Mr. Johnstone's pointed wire. The wire being a conductor and pointed, reduces the resistance of the path between the inner and outer coatings of the jar, and permits the electricity to flow between them, even when the potential is much below its maximum with the ordinary arrangement of the jar.

Mr. Johnstone, in his book, also discusses the classical experiment employed to show the phenomenon of electrostatic induction, in which an insulating conducting cylinder is placed with one end near to a conductor charged with electricity. He found by his insulating flame that a current of electricity was passing through the air space between the two conductors, and his explanation of the phenomenon is that a current is continually flowing along the line of conductors, which current is dammed back, as it were, by the greater resistance of the air, and appears as a charge of positive electricity at one end of the insulated cylinder. We have not been able to make any experiments to confirm Mr. Johnstone's statement as to the passage of electricity through the dielectric air, but at least in one of his deductions, namely, that the potential is greater at one end of the cylinder than at the other,

he is wrong. He may easily convince himself of this by connecting the opposite ends of the cylinder to the two poles of a quadrant electrometer.

We think that Mr. Johnstone is right in his view that there is only one kind of electricity, the so-called negative electricity being due to a diminution of the normal charge. Whether or not he is right in his view that electricity is matter, depends greatly on what definition of matter he adopts. It is impossible also, we think, to prove that he is wrong in supposing that, under certain conditions, electricity (if it is a substance) passes through the substance of a dielectric. All that is necessary, however, to support the modern theory of induction is, that during its passage it stores up the whole of its energy in an elastic dielectric in such a way that the dielectric has the power of restoring it more or less completely to the electricity during discharge. The controversy as to whether induction is real or imaginary, appears to us to resolve itself into a logomachy.

---

## ELECTRICAL STANDARDS.

---

THE necessity for determining accurately the value of the electrical standards is growing day by day, and it seems time that energetic steps were adopted to have the matter taken in hand. The work of carrying out the determination is by no means easy, but so many practical suggestions have been put forward, and so many preliminary experiments made by various workers, that the chances of obtaining reliable results are vastly greater than they were a few years ago. Some time since, Lord Rayleigh advocated certain work which he considered necessary to be done before the conditions for an accurate determination of the value of the ohm could be advantageously discussed. This work, at least one of the papers read before the British Association, stated had been accomplished, and therefore, in view of the practical necessity for an authoritative determination having arisen in connection with the standardising laboratory, the author thought the time ripe for the whole matter to be dealt with. In view of the extreme importance of the subject, it seems reasonable that a Government grant should be obtained for the purpose, and this would, we believe, be largely supplemented by the free-will offerings and labour of those interested. In view of the fact that the adoption of a correct standard is an international matter, it is of great importance that the work be carried out in this country as thoroughly as possible, no expense being spared to effect the required object in a manner which shall disarm criticism. If this is not done, we shall be liable to have the results questioned by others who have been privately working, and who may claim that they have arrived at their determinations by methods and with apparatus equally efficient with those employed by our own scientists. In fact, we believe that it was some such argument as this which led to the absurdity known as the legal ohm, which, however, fortunately never came into actual use.

Waste in  
Transformers.

SIR WILLIAM THOMSON'S B.A. paper on Anti-effective Copper in Conductors is not only of scientific interest, but has, in addition, great practical value. The author shows that though the ohmic resistance of a conductor may be reduced as its cross section is increased, a thickness is soon reached at which, notwithstanding the reduction of the ohmic resistance, an addition of copper causes an increase in the heat generated by an alternating current in the conductor. This results from an unequal distribution of the current throughout the cross section of the conductor which is caused by parasitic currents generated inductively in its mass. After a certain point, then, not only does increasing the copper fail to give an advantage, but it is productive of actual loss, or becomes, as Sir W. Thomson puts it, anti-effective. These considerations are specially applicable to the case of coils consisting of several layers of wire laid above each other in series, as in the various forms of transformers; but the author shows that a remedy for the evil indicated may be found in employing a stranded conductor which has its separate wires insulated from each other by a slight coating of varnish or other suitable material. In his paper on Alternate Currents in Parallel Conductors, Sir William Thomson considers the effective resistance offered by conductors to alternating currents or rapid discharges of electricity.

Permanent Magnets.

MR. PREECE'S interesting paper "On the Character of Steel used for Permanent Magnets," gives the results of a large number of experiments on magnet steel made at the Post Office. It will be seen from the figures that the French specimens are much superior to those supplied by English makers, as far as strength is concerned; at the same time it is possible that in the former the magnetism may be less permanent, and we believe we are correct in saying, that in instrument work, permanence is of quite as much importance as strength. We are pleased to note that Mr. Preece means to further investigate the matter, when the point to which we have referred will doubtless receive full attention.

Effect of Electricity on  
the Human Body.

MESSRS. LAWRENCE AND HARRIES have supplemented their paper read before the Institution of Electrical Engineers, by one read at the B.A. meeting, in which further experiments are recorded. This time they used the currents from actual lighting circuits, and obtained results widely different from those given in their previous paper. The figures given in Table C, showing the variation in the strength of the current with the contact area, seem very extraordinary, and demand further elucidation. That there is a relation of some kind is undeniable, but from the readings it seems impossible to formulate any definite law respecting it. The paper and the conclusions at which its authors arrive are before our readers, who can, themselves, extract from it such information as they think may be of service. The main conclusions are that an alternating current of 100 volts sends through an ordinary individual, touching the poles with his hands, a current which produces muscular fixation, thus depriving him of the power to release himself, while by a direct current no such

effect is produced. The obvious moral is—Don't touch the poles at all, advice which most users of electricity will be pleased to take.

Electrical Exhibits  
for 1893.

THE National Electric Light Association held its twelfth convention at Cape May and deliberated upon topics of common interest to the electrical fraternity. As usual, many of the questions under discussion were more or less of local importance, but those which may claim universal attention were by no means plentiful. Prof. John P. Barrett read a paper on "Electrical Industries and the World's Fair," setting forth the deficiencies in matters of electrical exhibits at the Paris Exhibition of 1889, and he exhorted his hearers to make the utmost effort for a gigantic display of American electrical machinery at the proposed great exhibition of 1893, to be held at Chicago. At the present time there are in the United States some 430 separate companies and individuals who may be expected to apply for space, but everyone of this number will probably defer action until the last possible moment, unless the importance of securing the necessary space and having the exhibit in readiness within the appointed time, is impressed upon them. Some of the manufacturers will have to be coaxed into making exhibits, while others will hesitate on account of the expense entailed. The author criticised the methods adopted at Paris and other exhibitions, and suggested that exhibits should be arranged according to the various types of apparatus, irrespective of the main display of the exhibitor. That is, to place all telephone apparatus and everything thereto appertaining in close proximity; the same with telegraphic apparatus, arc lighting dynamos, incandescent machines, motors, &c. The carrying out of such a plan will, of course, give two or more separate exhibits to each manufacturer, and thus entail additional expense, both in the matter of suitable furniture, and possibly in the matter of attendance; but all this additional outlay would be more than returned in the excellent results attained, and in the simplifying of the study of any particular type of apparatus. This suggestion has scarcely the merit of novelty; at English exhibitions, especially those of an engineering character, this method of grouping allied subjects has frequently been carried out as far as it was possible to do so.

Prevention of  
Accidents from  
Electric Currents.

"WHEN the development of electric currents, on a large scale and at small cost, first became possible by reason of recent discoveries, the question of the dangers to life and property attending their use was brought prominently before the public, just as the dangers attending the use of steam, of rapid locomotion on railroads, and of dynamite were brought to the attention of the world when these powerful agencies first left the experimental laboratory of the chemist or engineer to take their part in the ordinary labour and business of life." With these words Prof. Henry Morton opens a paper on "The Dangers of Electricity." He maintains that a much smaller number of people are killed or injured by high pressure boilers than by low pressure ones; the same relation has been found between dynamite and gunpowder, the former having largely reduced the proportion of accidents and injury as compared with the work done. Without these "dangerous" agencies

man would be reduced to the lowest condition of savagery, when he would be at all times helplessly at the mercy of the "elements," or the blind forces of nature. Referring to accidents from high tension currents, the author states that the "Employer's Liability Assurance Corporation" had collected a mass of material from a great variety of sources, and it has formulated a series of rules for the protection of those employed in erecting and operating electric apparatus involving the use of dangerous currents. These rules have been examined and approved by several prominent electric companies, and so far it would appear as if no accidents have resulted from the use of electric currents where these rules have been followed, and that most, if not all, the accidents which have occurred would have been prevented had these rules been obeyed.

#### Secondary Cells.

IN his concise paper before the British Association, Mr. Barber Starkey sets forth the history of his discovery of the effect of carbonate of soda upon the sulphate in lead sulphuric acid cells. We have repeatedly referred to this subject in our columns, and need only mention now the present statement of Mr. Barber Starkey, which is to the effect that according to his experience it is no longer necessary to pass a heavy current through cells to prevent sulphating, and he suggests that it would be more satisfactory to use larger cells than has hitherto been customary for stationary work, and both charge and discharge them at a considerably lower rate than at present recommended, thereby enormously increasing the life and efficiency of the cells, and leaving a large surplus in case of emergency. His own cells have been treated in this way, and they have not materially deteriorated after nearly five years' use. The author also recommends the use of soft lead grids in preference to those of a hard and brittle alloy. The desirability of this we were the first to point out some years ago, when lead-antimony grids came into fashion, giving substantial reasons for our assertions, and, we believe, the practice of using the latter has been abandoned by those who formerly advocated it. If it is desired to use separators between the plates, a very simple and cheap way to make them is to use perforated porous paper which has been saturated in melted paraffin wax, this, says the author, stands well in dilute acid, and he had some in use for several years. Referring to his method of preparing a solid electrolyte of plaster of Paris 1, sawdust  $2\frac{1}{2}$ , and dilute sulphuric acid until set into a compact porous mass, Mr. Barber Starkey relates that the cells filled in this manner and used on the Barking Road trams have apparently been a failure, although he had some success with this process in his own set of batteries. The defect of this arrangement would appear to be that it must hinder the free circulation of the liquid, and also add to the internal resistance of the cell, whilst, on the other hand, it prevents the plates from buckling, retains the active material firmly in its place, preserves the plates from injury and makes the cell very portable.

THERE are in the United States some 15,000 electric motors in use for almost every conceivable purpose, and the great majority of these are connected with central stations. One of the difficulties experienced by central

station managers was the charge that should be made to consumers for the use of electric energy. If all these motors were in constant use and giving off constant power, then it would be an easy matter to determine a fair rate for the current consumed, but few, if any, motors are doing constant work, some are at times much overloaded, others are never worked to their full capacity, and, as a rule, machinery in workshops must stand idle for considerable periods when work is being removed, prepared, or set in machine tools. Mr. H. L. Lufkin has made an accurate study of the conditions which obtain in various trades relatively to the average power consumed by machinery, and he has set forth the results in a series of diagrams illustrating the paper he read on this subject at the National Electric Light Convention. These diagrams illustrate the fluctuations in the current supplied to motors in actual practice, they give the maximum, minimum, and average readings, the current consumed in driving the shafting, and the peculiarity of the records of motors operating lifts. In some cases it is shown that over 60 per cent. of the average power developed by the motor is employed solely in overcoming the friction of shafting, where one large motor drives a number of machines. This would point to the advisability of using a number of smaller motors driving individual machines, and it is merely a question of relative efficiency between small and large motors. In a typical case of a 15 H.P. motor working lithographic presses the maximum rate consumed is 10 H.P. The user is given a 10 H.P. rate at \$60 per month, but the average power consumed is but 6.7 H.P., therefore he pays \$9 per H.P. per month instead of \$6 per H.P. for the power actually consumed. This difficulty, we think, could be easily overcome by attaching to each motor circuit a special meter. Meters of the ordinary kind for electric lighting are complicated and expensive, owing to the wide range they must have. Now a 70-ampere motor could never use less than 10 amperes, even if running an idle lathe or shafting, thus the extreme range would be about 1 to 7. Such meters could be made very cheaply and yet be perfectly accurate within such narrow limits; by this means both suppliers and consumers might be satisfied.

#### The West India Cables.

THE resuscitation of the scheme for a direct cable between Spain and Cuba, has given the Spanish technical press an opportunity of again inveighing against the concession granted in 1868, to the West India and Panama Telegraph Company, for a period of 40 years. This concession was given with the intention of making Cuba the centre of all the West India telegraph communications, the wording being to the effect that direct submarine telegraph lines should be laid between Cuba and Puerto Rico (two Spanish islands), and radiate from Cuba to Panama, to Mexico, and to South America. The telegraph company, however, instead of complying with the stipulations of the concession, laid a cable from Cuba to Jamaica, from Jamaica to Puerto Rico, from Jamaica to the isthmus of Panama, and connected up South America *via* the other West India islands, and in this manner declared the clauses of the concession fulfilled. The article from which we quote says:—"It is with shame that we must confess that this contempt of contract, this injury to national interests was consented to by the Spanish Administration." We are told that, not content with this infraction of the

most vital clauses of the concession, the telegraph company, jealous of its privilege, has taken every possible measure to prevent any other persons establishing a direct communication between Cuba and Puerto Rico. In view of the fact that the company has in no way fulfilled the stipulations of the contract, the concession must *ipso facto* become null and void, and it is the duty of the Spanish Government to further in every way the laying of a cable between Spain and Puerto Rico, and between Puerto Rico and Cuba.

## B.A. Ethics.

JUDGING from several letters which have recently appeared in *Nature*, it seems that the time is not far distant when some radical changes will be made in British Association procedure. The points touched upon in these communications, however, do not stand alone, for a comparatively new departure in the ethics of "learned" bodies has recently been made, which, if further developed, will scarcely tend to raise the standard of associations sanctioning such questionable policy. Two at least of the papers read before the British Association meeting had previously appeared *in extenso* in one of the scientific journals, and naturally it often occurs that the same individual submits papers on a certain subject before two or more societies. As a rule, the author has good taste enough to vary the text, and to introduce into each some special point of interest not common to both. But to write an article in a journal, get the credit, if nothing else, and subsequently present this very same article in the form of an original paper to the B.A., indicates motives which Mr. S. A. Varley would characterise as of questionable morality. Considering the publicity which is given to the deliberations of the British Association, there is not even the excuse of a desire for self-advertisement, and we can only put down such conduct either to a want of originality on the part of the authors, or to an utter indifference to the object which brought the association into existence. Had the authors been small fry there is but little doubt that their contributions would have been tabooed, but in the same way as there is said to be one law for the rich and another for the poor, so it seems that science panders to the great at the expense of its more humble devotees.

## The Latest Millionaire.

THERE is one means by which the B.A. meeting is rapidly bringing itself into world-wide notoriety, and which for several years past has been getting more and more ludicrous; we allude to the strange hallucinations under which Mr. W. H. Preece seems to labour and which give rise to those frequent utterances which at once make him the comic man of the party. In the daily press reports of Section G, last Tuesday, we noticed that Mr. Preece spoke of the extreme importance of preventing dangers to the public. During a lifetime associated with electricity, he believed he had experienced *a million shocks*. Small as were some currents, they possessed a certain amount of danger from shock or fright to the individual affected, and might perhaps cause stoppage of the action of the heart. Now, taking Mr. Preece's age as 56, a trifling calculation would apparently show that he has been receiving shocks, more or less severe, during all these long years at the rate of 50 per day, and yet he survives. But seeing that he did not enter the electrical profession until he was 18 years of age, and making

due allowance for Sundays and B.A. meetings, he has undergone muscular contractions during business hours at the rate of say, one in every five minutes, knocking out the decimals. The genial electrician of the Postal Telegraph made some further remarks upon skin resistance, and it is to be hoped that next year he will be able to place before the meeting a precise definition of both a thin and thick-skinned individual. We fear, however, that if he does not curb his too lively imagination, he will sooner or later receive a shock, not necessarily electric, which will seriously discount his remarkable gifts as a lecturer on science, even if it falls short of stopping the beating of his large heart.

## Newspaper Technics.

THAT the "Silly Season" has not yet come to an end, is evidenced by the correspondence in the *Daily Telegraph* on electric carriages, where the advisability of having private vehicles propelled by electricity is being as gravely discussed by people who know nothing whatever of the subject, as is that more complex matrimonial problem, originated by a recent breach of promise case, by those who apparently know still less. Let us first see electric tramlines commercially successful before troubling our heads with minor matters which can very well wait their turn until the time is ripe, if it ever comes, for dealing with them.

## A Graceful Compliment.

PROF. OLIVER LODGE must have experienced a proper degree of pride during the past week. Not only was a paper of his, previously published, read at the B.A. meeting, but an admirable portrait of the author of "Modern Views of Electricity," which probably excited the envy of all his less-favoured compeers, appeared as a supplement in an esteemed contemporary, the price of which, in honour of the event, or more probably in the true interests of science, was raised 50 per cent.

## Fire Risk Rules.

THE Phoenix Fire Office Rules have met with another rebuff at the hands of Mr. Wilson Hartnell, who, in his B.A. paper, recommends the adoption of those compiled by the Institution of Electrical Engineers. We hope soon to be able to devote special attention to this matter, the importance of which is shown by the completely opposite views taken on existing rules.

## The Georgetown Telephone Exchange.

WE have received an interesting account of the opening of the new telephone exchange in Georgetown, British Guiana, which is arranged for 200 subscribers. The whole of the work, which commenced last December, has been carried out by Creole labour, superintended by the Government Electrician, Mr. Samuel Vyle, who may perhaps be remembered by readers of the REVIEW of some years' standing. From what we can gather, Mr. Vyle has made himself quite indispensable in his sphere of operations, and appears to have become immensely popular with the Georgetown community.

## ELECTRIC LIGHT IN NEWSPAPER OFFICES.

THE advantages of the electric light are probably more fully to be found in the establishment of a daily newspaper than in most places, and the progress of the light in printing establishments throughout the country has become very marked. The latest installation of which we are aware is that at the offices of the *Manchester Examiner and Times*. This is an old-established paper, but it has of late changed hands, and the present proprietors have been making thorough changes with the view of enhancing their property, and one has been in installing the electric light in the place of gas; gas, however, is highly valued in this establishment, for it is used with one of Crossley's largest sized engines for driving the various printing machinery.

The installation in its present form consists of over 200 incandescent lamps of 16 C.P., but a larger number will be shortly added. The entire work has been carried out by the Manchester Edison-Swan Company, Limited, which has done the principal electrical work in this district for many years.

The lamps are placed throughout the building from the printing and paper rooms, where there are 32 lights, to the top, where over 100 lights are placed in the composing room. The offices and publishing department on the ground floor, the editor's and other rooms, are fitted up and appear to have been arranged with the view to extra light and comfort. The dynamo is of the company's Lancashire type, having a capacity of 300 lights, at an E.M.F. of 100 volts, with 900 revolutions per minute. It, however, is arranged, in this case, to run at 600 revolutions per minute, giving an output of 220 to 230 lamps at 100 volts. The engine is a special vertical electric light engine, by Marshall, of Gainsborough, with double fly-wheels, complete, for this special work. The speed is 150 revolutions per minute. The boiler is of the locomotive type, also by Marshall, arranged with the flue drawing downwards, and specially arranged to suit the confined situation it has to work in. The engine has been so fixed and arranged that in case of any accident or breakdown to the gas engine, it can be coupled up to drive the printing plant and other machinery. The wire and cable used throughout the installation is of Glover's double rubber insulation, and the capacity of the copper is calculated on the basis of about 750 ampères per square inch. The cut-outs, switches and holders, are all of the Manchester Edison Company's own patent type. The fittings are generally of a plain description, most of the shades being 9 in. flat opal. The work has been well carried out by the staff of the company, under the able supervision of their manager, Mr. M. P. James Fawcus, A.I.C.E., to whom the credit of planning out the entire arrangement is due. The installation has been started running within the last few days, and is working very successfully.

COMMUNICATIONS FROM AUSTRIA-  
HUNGARY.

[FROM A CORRESPONDENT.]

AS I already announced to you on a former occasion, the town of Teplitz purposes erecting electric works for lighting up this celebrated watering place. The town has resolved not to renew the contract for street lighting with the gas-works (which expires on August 1st, 1891), but to erect an electric central station at its own expense, and to carry it on as a municipal electric works. Concerning the right of the town to annul the agreement with the gas company, there prevail different views, and it may probably lead to litigation between the town and the company. Meanwhile, the municipality has already applied for proposals to different firms, e.g., Siemens, Ganz, Schuckert, Egger, Krenetzky, and Waldoek, jun., Wagner, without loss of

time. Several proposals have been already made to the town, both on the part of the gas company and of other contractors, applying for a concession for supplying an electric current. One undertaking even proposed to light up Teplitz, Aussig, and other towns of the district, from a common central station. The town, however, has declined all these offers, and has voted the sum of 300,000 florins for the erection of a municipal station.

Two localities, both within the town, had been proposed for the works. Subsequently it was judged better to erect the works outside the town, close to a coal-mine, so that the coal could be at once utilised on the spot without the cost of carriage. The coal-mine is about 600 metres distant from the town and about two kilometres from the most remote buildings to be lighted up. As the gas agreement expires on August 1st, and it cannot be expected that, in the case of its non-renewal, the gas company will further undertake the public lighting, the town must be prepared to have the electric works ready for action by that date.

A very interesting process between the city of Vienna and the Vienna Imperial Continental Gas Company has been just decided. The dispute did not refer to the carrying out of any definite claim, but formed a so-called "prejudicial accusation." The city wished to have a clear decision as to its future position with regard to the gas company, i.e., whether the company, after the expiry of its agreement, was entitled to leave the gas mains in the soil of the city—in other words, if the city, after such expiry, would be authorised to insist upon the removal of the gas mains. The Supreme Court decided that the Vienna Imperial Continental Gas Company, after the expiry of its agreement with the city, is bound to remove the mains and pipes from the ground. This decision holds good, of course, for undertakings for electric lighting with underground cables, and is, of course, very important. All such undertakings, in default of an express stipulation to the contrary, in virtue of the above decision, will be bound to remove their nets on the expiry of their agreements.

The Buda-Pest Tram-line Company (Siemens and Halske) has applied for a concession to lay down an electric tram-line on the right bank of the Danube, which subsequently, after completion of the fourth Danube bridge (recently projected), is to be joined to the net of electric tram-lines on the left bank. The new line is to terminate in a mountain line, and lead up to the celebrated Blocksberg, from which there is a splendid view of the city and its vicinity, and which, in the last few years, has become a very favourite resort of the public of Buda-Pest.

The Imperial Court management has resolved to provide all parts of the royal Hungarian castle, situated very picturesquely on the citadel, with electric lamps. If an electric installation is erected in Buda-Pest at an early date, these lamps are to be attached to the general net. If the execution of this project is too tedious, a special lighting station is to be erected for the castle, though outside its walls.

## THE DANGERS OF ELECTRICITY.\*

By Prof. HENRY MORTON.

WHEN the development of electric currents, on a large scale and at a small cost, first became possible by reason of the discoveries of Faraday, Wilde, Gramme, Siemens and others, the question of the dangers to life and property attending their use was brought prominently before the public, just as the dangers attending the use of steam, of rapid locomotion on railroads, and of dynamite were brought to the attention of the world when these powerful agencies first left the experimental

\* A paper read before the American National Electric Light Association, August 20th, 1890.

laboratory of the chemist or engineer to take their part in the ordinary labour and business of life.

In each instance alike there was a class of people who took the narrow and partial view, that if an agency was dangerous it should be excluded altogether from public use, or, what amounted to the same thing, be surrounded with such exclusions and limitations as would rob it of nearly all its capacity for usefulness, and restrict all possibility of advance and development in its application.

Thus laws were actually passed in England on the first introduction of steam, limiting the pressure in boilers to 30 lbs. on the square inch.

The first railroad charter contained a clause limiting the speed of trains to 12 miles an hour, and when a speed of 30 miles was suggested, it was ridiculed in a prominent journal of the day as an idea simply insane, and it was said that people would just as soon be persuaded to allow themselves to be fired out of a cannon as to be hurled along at such fearful velocities, which would, without doubt, have the most disastrous effects upon the circulation of the blood and other vital actions.

Some of us can also recollect the excitement produced and echoed in the press on the introduction of dynamite, and the stringent laws regarding its transportation, which in many cases only increased the danger to the public by occasioning its surreptitious conveyance in passenger and ordinary baggage cars.

We shall have to be very young indeed not to remember the great popular excitement brought about by the daily press when electric lighting first appeared in the streets of New York, and when flashes of flame were described as proceeding from a horse that had run against an electric wire.

In all the older instances matters have settled themselves in accordance with the laws of human progress and the diffusion of intelligence, and we now have boilers running at pressures of 140 lbs. and upwards, trains going more than a mile a minute, and gunpowder largely superseded by dynamite.

What is more, the accidents and injuries actually produced by these several agencies have been vastly less than those caused by the things which they replaced.

A much smaller number of people are killed or injured by high pressure boilers than by low pressure ones. How rarely do we hear of the explosion of locomotive boilers, which usually carry 140 pounds pressure.

The accidents to express trains are as nothing compared to those occurring with freight trains, and the loss of life and injury to passengers by rail is insignificant in its percentage to the number carried, when compared to similar loss and injury incurred in the days of stage coaches.

The same relation has been found between dynamite and gunpowder, the former having largely reduced the proportion of accidents and injuries as compared with the work done.

Two lessons are very plainly taught by the facts of history above alluded to.

First: The world is not going to be frightened away from a new and valuable source of power by the circumstance inseparable from the very nature of all powerful agencies, that it is dangerous if not adequately controlled; but, on the contrary, will develop the new power to an ever-increasing and, therefore, more (possibly) dangerous intensity.

Second: Intelligently managed and controlled, the most powerful and, therefore, in a sense, dangerous agencies, become the most efficient protectors and servants of man, and not only aid him in his mission of subduing and utilising nature, but actually protect him in his work.

Without these "dangerous" agencies man would be reduced to the lowest condition of savagery, where he would be at all times helplessly at the mercy of the "elements," or the blind forces of nature.

With them he not only defies and subdues the beasts which would otherwise be his superiors, but even conquers and renders tributary to his comfort and advance-

ment those vast forces which control the entire matter of the universe.

Applying these lessons taught by the past history of the world in parallel cases to the problem of the distribution and use of electricity, we see, in the first place that the way to deal with its dangers ought not to be the timid, obsolete way of prohibition, or of unintelligent restriction, such as that which proposed the exclusion of locomotives from railroads, or the limiting of their speed to 12 miles an hour, but the sensible way of providing adequate safeguards to the new power, and with these allowing it to follow its natural line of development and growth into higher and higher ranges of intensity and consequent efficiency.

It is too well known to all to need statement, that the methods thus pointed out by history and taught by experience have not been by any means universally advocated or followed, and that while many have loudly demanded the exclusion of powerful electric currents, the limitation of their intensity to what they suppose to be necessarily harmless ranges, the users of such electric currents have in too many cases neglected the most obvious precautions.

It is only fair to say, in explanation of this latter statement, that this neglect has in many cases been brought about by obstructions thrown in the way of good work by those who were exciting themselves for the total abolition of dangerous currents, and who, like certain "total abstinence" advocates, objected to every mitigation of the evil they attacked, because any such improvement weakened their case against it.

As regards dangers to property from fires, the matter fortunately fell at an early period into the hands of the Board of Fire Underwriters, who, in a judicious and business-like way, investigated the subject and formulated such rules as have proved eminently satisfactory, and have proved that under proper regulations as to good work and means of protection, electricity is by far the safest means known to us for the distributing and development of light, so far as "fire risks" are concerned.

In view of the satisfactory results thus obtained, I regard it as a fortunate circumstance that the other part of the problem, namely, that relating to dangers to human life, has been recently taken in hand by a similar organisation known as the "Employer's Liability Assurance Corporation."

This association, after collecting a mass of material from a great variety of sources, has some time since formulated a series of rules for the protection of those employed in erecting and operating electric apparatus involving the use of powerful, and, therefore, dangerous currents. These rules have been examined and approved by several of the managers of prominent electric companies, and, so far, it would appear as if no accidents have resulted from the use of electric currents where these rules have been followed, and that most, if not all, the accidents which have occurred would have been prevented had these rules been followed and obeyed.

Having had something to do with the framing of these rules, it is my chief object in presenting the present paper to secure their criticism by those bestable to perceive their imperfections, and such suggestions as may lead to their beneficial modification or extension.

I therefore quote them as follows:—

First. Do not touch or handle any electric wire or apparatus of any sort while standing on the ground, or while in contact with any iron work, gas or water pipe, or stone or brick work, unless your hands are covered with rubber gloves, and you are provided with such properly insulated tools as have been declared to be safe and in good order by the electrician or other competent officer of this company.

If it is at any time necessary to stand on the ground, or on any surface not insulated from the ground, while handling electric wires and apparatus, rubber boots or an insulated stool should be used.

In moving wires, hanging on, or lying over, electric light wires, lamps or fixtures, use a dry hand line,

Second. Never handle any electric wire or apparatus with both hands at once when this can be avoided, and, if it is necessary to do so, be sure that no current is present, or that one or both hands are protected by rubber gloves or other efficient insulation.

Third. When handling line wires, treat each and every wire as if it carried a dangerous current, and under no circumstances allow yourself to make contact between two or more wires at the same time.

Fourth. Never open a circuit which has been in use without giving notice to the superintendent, or whoever is in charge, of your intention to do so, and at the same time request that the same line be opened at the main station, and kept open until you have given notice that your work on that line is complete.

Fifth. In the dynamo room never go near the belts or dynamos, nor touch any apparatus unless you are fully informed and instructed how to do so.

Tools used by linemen should be provided with insulating handles of hard rubber or other equally good insulator. It is the duty of each lineman to look after his own tools and see that they are in good order, especially as to their insulation.

Sixth. Lamp trimmers and others engaged in the care of lamps must see that the switch putting the lamp in circuit is turned off before they handle the lamp in any way.

Seventh. In construction work, a space of at least 20 inches must be left between the holes for pins on the cross arms, so that a lineman may get to the top of the pole and work without danger.

The same insurance association has collected the authentic records of a number of so-called "electric accidents" or accidents happening to the *employés* of electric companies. I have now before me the abstracts of 91 such cases.

The first thing that presents itself in looking over this set of abstracts is that very few of the accidents are in any way attributed to electricity directly, but would have occurred had the establishment in question been any kind of a factory where power was being used, or any place where heavy objects were being moved. A few examples will illustrate this, thus:

"No. 1. Whilst steadying with a pike-pole a large electric light pole which was being placed in position, a passing 'low-gear' belonging to the Standard Oil Company ran over ankle."

"No. 2. While assisting in hoisting a stick of lumber from the street to the second floor of electric station, was injured in right foot by having the stick fall upon it."

"No. 9. Was going to dynamo, stepped on iron plate temporarily covering a belt hole in floor. The plate tipped and he fell partly through the opening, injuring himself internally."

"No. 17. Was oiling rocker shaft of engine near fly-wheel; leaned back too far and was struck on head by spider of fly-wheel."

The above are fair samples of the rest, and, in fact, out of the 91 cases but 15 (or about 16½ per cent.) have any direct relation to electricity.

As I have already mentioned, of the 15 cases in which the injury was in any way caused by electricity there are none in which the action would not have been avoided if the above quoted rules had been observed. Thus, beginning with first in order as arranged in the abstracts, all before it having no direct connection with electricity, we have:

"No. 11. While removing the wire from a Brush dial or regulator which had become short-circuited, was slightly burned on two fingers of right hand."

In this case the beneficial effect of rule No. 2 was manifestly expressed, and had the spirit of rule 7 been complied with even the slight injury experienced would have been avoided.

The next in order is:

"No. 20. Was putting carbon in electric lamp which was out of order and failed to burn. Received charge of electricity, which caused him to fall down from step-ladder on to steam radiator. Two ribs broken."

This would clearly have been avoided by an observance of rule 7.

Time will not permit me to quote all the 15 cases, and I will, therefore, only repeat that they would, all of them, have been avoided by a strict observance in form and spirit of the above quoted seven rules or directions.

Of course I do not mean to imply by this that these rules are perfect or complete, but only that they seem to be in the right direction, and to furnish a starting point from which further developments may proceed.

No one having even an elementary knowledge of electricity as it existed 10 years ago, needed or needs to be convinced of its power to do harm where all safeguards are removed, and the occasional declarations of its harmless character which have been uttered can only be accounted for by reference to that combative disposition which impels some minds always to take a view in opposition to any which may be expressed, and gives birth now and then to a book or pamphlet disproving the law of gravitation or the solar origin of light and heat. To say this is, however, far from agreeing with the other extremists who would banish electricity from our daily walks and occupations, or place it under restrictions which *might* render it harmless, but which *certainly would* render it relatively useless for the countless purposes in which its efficiency demands its full development.

The true opinion is that which is supported by past experience, and which advocates the fullest developments of power to which this agency can attain, combined with the use of all the means of protection by which human intelligence can protect itself while using to the utmost this potent and, therefore, dangerous weapon in our victorious contest with the inimically destructive forces of nature.

## UNDERGROUND CONDUCTORS IN MADRID.

THE *Ciencia Electrica* of Madrid, is publishing a series of articles, written by Senor J. Casas Barbosa, formerly the manager of the Sociedad Matritense de Electricidad, under the title of "Electricity in Spain." The electric lighting of Madrid naturally claims precedence, and the articles in question deal, for the present, with the operations, in that city, of the company above-mentioned. Especial mention is made of the installations in the gardens of Buen Retiro and in the park of Buenavista, including, in the latter, the illumination of the Ministry of War.

In reviewing the results of the distribution of current by means of overhead wires, the conclusion is arrived at that this method is altogether unsatisfactory, experience showing that it is untrustworthy, precarious, and only suitable for purely temporary necessities.

In view of the uncertain nature of overhead lines, the Sociedad Matritense turned its attention to the question of canalisation and underground conductors.

Many difficulties were encountered in realising the proposed change, among them being the exclusive authority over the public roads assumed by the gas company, and which had been tacitly assented to by the authorities and the public, though unsupported legally.

In the year 1883, Senores Dalman and Losada obtained the right of canalisation over a considerable area, but the experiment was actually extended to only the very limited distance of about 2 kilometres. The system consisted of a conduit of Portland cement, containing two parallel semi-circular troughs. The conduit was covered in with blocks of cement. Wires covered with tarred tape were laid down, but on account of the damage caused to this covering by haulage and the frequent presence of water in the conduits, the system failed completely.

By degrees the tape-covered wires were replaced by others covered with impregnated yarns and enveloped with lead, but the porosity of the metal caused frequent disasters, although, in some cases, the experiment

was tried of placing a double covering of lead over the wires.

In 1886 the condition of the cables had become so bad that it became necessary to attempt some further remedy. Pieces of wood impregnated with tar were placed at short intervals along the conduit. The wood was shaped to fit the semi-circular troughs, and on the upper edge slots were cut to receive the cables, which were thus suspended clear of the sides and bottom of the troughs. After six months' service it was found that excessive leakage prevailed over the system, and on examination it was discovered that an electrolytic action had been set up at every point where the cable was supported by the wood. These pieces of wood were consequently replaced by well-lacquered porcelain supports, which have given very much better results.

The author considers that a lead covering to the cables frequently constitutes a serious danger, and he goes on to say that, in his opinion, a bare copper bar, suspended by means of insulators from the arch of a conduit, presents the best method of insulating an underground conductor. At the same time, the case is quoted of the Barcelona installation, where bare copper bars were placed underground in the manner above indicated. The system signally failed, owing to the presence of water in the conduits.

the travelling over a slack rope would prove more interesting and attractive to the general public than a rigid rail.

Telpherage has taken some years to bring to its present perfection, but during that time the difficulties, which have naturally arisen in an undertaking of such a character, have been successfully met, and the particulars now made public seem to be convincing of the simplicity and reliability of this, the most modern method of transport.

The system comprises arrangements for the transport of a wide range of material, from minerals and heavy freight to light packages, the lines being constructed for the particular purposes for which they are required. These lines partake of the same general character, the practical effect being an overhead line, with carriers specially suited for the employment of electricity in the transmission of the power required.

The Edinburgh line consists of over a quarter mile of track, the flexible portion of it being constructed in spans of 50 feet, and the rigid ends in spans of 15 feet. The stand ropes on which the locomotive and carriages travel are of crucible steel, and  $1\frac{1}{2}$  inches in diameter. These are tightened, so that with a full load on the line there is a sag of about 2 feet  $4\frac{1}{2}$  inches on the spans covered by the train.

The arms supporting the stand rope are arranged so that they move in either direction, allowing the sag in

We would also point out that in an earlier portion of the article the author refers to the installations at the club "Union Mercantil," and at the theatre "Romea," where the conductors, underground cables covered with India-rubber, have given exceptional satisfaction, the lengths of circuits being, altogether, about 16 kilometres.

In view of the extensive experience which Senor Casas Barbosa apparently has had with different systems under various conditions, his opinion as to the efficiency of bare copper rods deserves some measure of attention on the part of those engaged in laying underground electric light wires. We may add that the climate of Madrid is, generally speaking, very dry, with extremes of heat and cold.

### CHEAP TRANSPORT.

THE Electrical Engineering Corporation of London and West Drayton, since securing the sole rights for the Telpher system of cheap transport, have been vigorously developing the system, and determined to put up a Telpher line on a practical scale at the Edinburgh Exhibition to show the most recent improvements, and to so arrange the line as to carry passengers, and demonstrate the advantages of the system for the transport of goods. As a rule, they recommend rigid lines for the carriage of passengers, but it was thought that

the rope to follow the train as it moves along, thus obviating any undue strain upon the posts themselves. The stand rope at its junction with the rigid rail passes from a special descent junction saddle, so arranged that the train rises from the rope on to the rigid rail without any jerk or other unsatisfactory movement. From the junction saddle it passes direct to a structure termed the abutment post; this is fastened to the substantial anchorages in the ground by flexible steel ropes 5 inches in circumference. The strain upon the ends of the stand rope with a fully-loaded train is about 5 tons, and the strain upon the anchorages about 8 tons.

The current is conducted along a conductor, which is not attached to the insulators on which it rests at any point, but merely rests upon them. From the locomotive a rigid arm projects underneath the conductor, but above the insulators, and slides along under the conductor, lifting it off the insulators as the arm passes them, allowing it to rest on them again after it has passed. This method of collection, which is recommended in the "Waller-Manville" system of electrical traction, is proving admirably satisfactory.

The train, as will be seen from the illustration, is a very practicable one; the cars, which with the plant and the rest of the equipment were made at the works of the Electrical Engineering Corporation at West Drayton, are built much in the fashion of railway carriages, each car having two compartments and holding four persons, and each compartment being entered from a door with a railway latch. The space

in the cars between the passengers is the same as is allotted on the District Railway in their second class coaches. The whole of the car is suspended by iron hangers from two bogie trucks, the bodies of which latter consist of iron castings resting on the axles of the wheels at each end, and the hanger does not depend directly from the body of the bogie truck, but rests upon two vertical springs contained in boxes on each side of the body.

The locomotive consists of what is termed by the corporation a swinging tub, and the motor drives a small countershaft, to one end of which is attached an electrical governor to maintain a set speed; the other end of the countershaft has upon it a chain wheel which drives directly upon a larger chain wheel contained on the upper frame. The motor is suspended from the upper frame by a hanger, so arranged as to allow the whole to swing, the swinging movement thus allowed not interfering with the motion of the chain, as it is a movement radially to the centre of the large chain wheel on the upper frame. The upper frame contains, in addition to the large chain wheel, two driving wheels with malleable cast iron tyres to grip the rope, each attached to a chain wheel driven from the shaft supporting a large central train wheel.

The working of the line has, up to the present time, given every satisfaction, and has elicited considerable attention.

SPAIN AND MOROCCO CABLES.

THE *Ciencia Electrica* of Madrid, publishes an article upon the long felt want of some speedy and trustworthy means of communication between Spain and her possessions on the northern coast of Africa, and cites as an instance of this necessity, the recent troubles at Melilla, a Spanish fortress and convict settlement on the Riff coast of Morocco.

It is pointed out that as a first step towards protecting Spanish interests in Morocco, the example should be followed of the English, who have laid a cable between Gibraltar and Tangiers. This step is all the more necessary, in view of the attacks so frequently made on the Spanish outposts, by uncontrolled tribes, there being no telegraphic communication between the various military stations, or with the Peninsula. Considering the urgency of the case, the cost of the proposed cables, though assuredly a considerable item, ought not to be looked upon as an insuperable difficulty.

The Royal Decree of August 14th, inviting tenders, contains full details of the scheme, and particularises the proposed lengths of cables, as follow :

	Shore end.	Heavy intermediate.	Inter-mediate.	Light inter-mediate.	Deep sea.	Totals.
Tarifa-Tangiers ...	6.0	10.0	6.0	8.80	...	= 30.80
Tarifa-Ceuta .....	6.0	12.0	4.0	...	...	= 22.00
Almeria-Alboran...	6.0	20.0	6.0	15.0	36.60	= 83.60
Alboran-Melilla....	6.0	10.0	6.0	10.0	18.80	= 52.80
Melilla-Chafarinas	6.0	6.0	9.0	8.15	...	= 29.15
Melilla-Alhucemas	7.0	20.0	6.0	15.0	36.60	= 84.60
Alhucemas - Peñón de Vélez .....	6.0	10.0	6.0	8.80	...	= 30.80
Totals.—N.M.=	43.0	90.0	43.0	65.75	92.0	= 333.75

With the exception of Tangiers, the proposed cables connect up no points of commercial importance, their *raison d'être* being purely political, and the attention now paid to the Morocco question is significant of a more active policy on the part of Spain. Fear of the results of French enterprise and influence, always a thorn in the side where Africa is concerned, has no doubt assisted towards the inauguration of a more determined course with regard to Morocco.

NOTES.

**Burton Backward.**—At a recent meeting of the Burton-on-Trent Town Council, the Gas Committee reported the receipt of the Parliamentary Electric Lighting Order, but added that they had as yet taken no further steps in the matter.

**The Electric Light at Huddersfield.**—At the last monthly meeting of the Huddersfield Town Council, it was reported that the sub-committee had considered the advisability of taking steps for establishing an electric lighting station, under the provisional order which the corporation had obtained, and had appointed the mayor, the chairman, the vice-chairman of the sub-committee, and Mr. Calvert to inspect the electric light systems in operation in other towns and to report thereon.

**Palace Lighting.**—The Emperor of Austria has decided that the electric light shall be introduced into his palace in Vienna, the Hofburg, where till now wax lights have generally been employed for the purpose of illumination. About 8,000 incandescent lamps will be required to light the building throughout.

**Execution by Electricity.**—A telegram from New York dated the 11th inst., reads :—"The writ of habeas corpus in the case of the Japanese Shubuya Jugiro, who was convicted of murder, and sentenced to be executed by electricity, has been refused. The counsel who resisted Kemmler's execution presented a writ declaring that the condemned man would be carbonised and tortured to death. The judge, in dismissing the writ, alluded to the sentence carried out on Kemmler which, he said, the United States Supreme Court had decided was legal."

**Telephonic Communication between London and Paris.**—The Hythe Town Council, on Wednesday, granted permission to the Postmaster-General to erect posts and wires in the borough.

**The Electric Light at Lewes.**—At a recent meeting of the local town council, the question of electric lighting was discussed. Mr. Farncombe, comparing the advantages of gas and electric lighting, said the Gölcher (New) Electric Light and Power Company, as notified in last week's REVIEW, proposed to give 240 lamps of 16 candle-power, and to light seven and a half miles of streets, at a total annual cost of about £600, as against £800 now paid for the 200 odd gas lamps. He believed the present gas mains only extended over about five miles and a half. If the council erected the plant themselves and capitalised the cost in the usual way, the total yearly expense of the electric light would be about the same as now paid for gas, while in the course of time the whole of the plant would belong to them and there would only remain the cost of maintenance. Men who had studied the subject, declared that where electricity had been introduced the gas companies had done better business than before. The contrast between electricity and gas was so striking that the gas consumers was compelled to go in for improved burners and more gas lights, consequently they burnt more gas. Several of the largest ratepayers in Lewes strongly urged that the electric light should be adopted. He saw a good many people, and he had not heard a single word against it. The corporation owned three sites that were available for the machinery to produce the electric light, and he was informed that their situation was admirably adapted for the suggested change. Further consideration of the matter was adjourned.

A strong opinion exists in favour of the adoption of the electric light, and it is understood that a public meeting will be convened by the mayor shortly, to go into the subject. Several of the borough officials, including the Medical Officer of Health, are in favour of improved lighting, while one large ratepayer has already expressed his desire to have the electric light laid on to his house.

**The Electric Light at Bristol.**—The Sub-Electric Lighting Committee appointed to visit certain parts of the country in search of information, has now reported to the General Committee. The last town visited was Bradford, in Yorkshire, where the corporation owns both the gas and the electric light, but only uses the latter for private lighting. The sub-committee recommends that the corporation shall take the electric lighting into its own hands, and that from 60 to 70 1,000 candle-power arc lamps should be erected in the main streets of the area comprised between Temple Meads and the Victoria Rooms, and College Green and Old Market Street.

**The Electric Light at Winchester.**—A short time since the corporation of Winchester advertised for tenders to light that city by electricity. Strangely enough, no reply has yet been received to the invitation.

**The Electric Light at Derby.**—At a recent meeting of the Town Council the Mayor proposed that a permanent committee, to be called the Electric Lighting Committee, be appointed until November next, and also annually on the 9th of November each year, with power to consider the provisions of the Electric Lighting Order, and to make such arrangements as the council might deem expedient. He further moved that it be a special order that the Electric Lighting Committee should consist of 11 members of the council, and the Mayor for the time being *ex officio*. The proposals were agreed to.

**The Electric Light at Nelson.**—The Nelson Gas Committee has instructed the gas manager to take the preliminary steps for permanently illuminating the principal streets of the town by electricity.

**The Electric Light at Dundee.**—At the last monthly meeting of the Dundee Gas Commission a statement was submitted showing that during the past four months the amount of gas delivered in Dundee was 65,976,700 cubic feet, being an increase of 9,656,400 cubic feet on the consumption last year. Mr. Henry Robertson stated that with a steadily increasing consumption of gas the board were apt to remain quiescent in regard to electric lighting; but he reminded them that there were at present a score of public works supplied with the electric light. Those who were supplied with the electric light were delighted with it. A letter from the Electric Installation and Maintenance Company, Limited, tendering its services for the construction and maintenance of electric works in Dundee was allowed to lie on the table.

**The Electric Light at Fareham.**—An experimental installation of the electric light for the illumination of the Fareham streets was made on last Friday night, over a portion of the system, by the Fareham Electric Light Company, the experiment being regarded as very satisfactory. The system adopted is the Thomson-Houston, and the currents are supplied from two dynamos located close to the steam flour mills. The Local Board has engaged to pay £500 per annum for the lighting.

**Private Electric Lighting.**—The residence of Mr. Matthew Stevenson, of Harrogate, has been recently fitted with a complete installation of incandescent lighting. The wiring and fitting were entrusted to Mr. E. C. Wallis, of Bond Place, Leeds. As this is the first private installation in Harrogate, no effort has been spared to make it successful.

**Ship Lighting.**—The R.M.S. *Dunnottar Castle*, the largest vessel in Messrs. Donald Currie & Co.'s fleet, made her trial trip on the Clyde last week. All modern improvements, tending to the safety and comfort of passengers, have been adopted, including an excellent electric light installation by Messrs. Siemens Brothers.

**Electricity v. Gas.**—A lengthy controversy over this subject, in connection with Fareham lighting, is taking place in the *Portsmouth Times*.

**Nothing to Fear.**—At the annual general meeting of the Sunderland Gas Company, recently held in Newcastle, the chairman said that for some years past he had made references to the electric light, but now he had nothing to say, as there was nothing to be dreaded.

**Aberdeen Hammermen's Exhibition.**—A recent addition to the attractions of this exhibition is a powerful search light, erected by Messrs. Macwhirter, Ferguson and Co., electricians, Aberdeen. The light is a naval projector, manufactured by Messrs. Crompton & Co., Chelmsford, having a 24-inch parabolic mirror and arc lamp for concentrating the beam, and is equal to from between 20,000 and 30,000 candles.

**Business Extension.**—Messrs. Elliott Brothers, the well-known electrical, optical, &c., instrument makers, of St. Martin's Lane, having found it necessary, owing chiefly to the large increase in the volume of their business to greatly add to their premises, are making a large addition to their existing works. The building, which is quite a feature in the new street leading from Charing Cross to New Oxford Street, has a handsome façade of fine Dorset stone, and is characteristically named "Faraday" House. The back of the new building abuts on the back of the old premises which face St. Martin's Lane, the whole occupying a space of about 10,000 square feet. Although most of the space occupied by the new building will be employed as workshops, &c., by Messrs. Elliott, a portion fronting on the new street is to be occupied by "The Electrical Standardising, Testing, and Training Institution." The success of the firm, which has such a world-wide reputation, is a matter for congratulation, and is well deserved.

**Edinburgh International Exhibition.**—The East of Scotland Engineering Association held a special session at the Exhibition on August 5th and 6th. Amongst the papers read was one on the "Protection of Buildings from Lightning," by A. R. Bennett, Vice-President of the Association, in which the effects of several recent storms in Scotland on buildings and telegraph wires were described; and one descriptive of the telephonic exhibits, by C. G. Wright, Fellow. The remaining papers dealt with the mechanical exhibits, the one by Prof. Elliot, on the Locomotive Annexe, being specially noteworthy.

**The Telephone in Great Britain.**—The Central News says the expiration of the telephone patents in England will begin on the 9th of December next, and the monopoly will soon cease, and the *Sheffield Daily Telegraph* observes that, "so far, it has hardly been possible to purchase a telephone at any price, the only way to procure one being by paying a rental of £15 to £30 a year. We understand that Mr. A. Erskine Muirhead, of Glasgow, has been urging the telephone company to adopt the 'Ader' or 'Berthon' telephone, which at this moment enables people over 600 miles apart to speak with ease. Mr. Muirhead has demonstrated the practicability of telephonically connecting the towns of Great Britain by means of existing railway wires, and with the help of Van Rysselberghe's system. There is thus nothing wanting but comparatively inexpensive apparatus to enable, say, London to converse by telephone with Birmingham, or Bristol, or Aberdeen, at the same moment as telegraphic messages are being sent over the same wires. This practice has been in operation in Belgium and France since 1882. As is well known, people can telephone from Brussels to Marseilles, *viâ* Paris."

**Notice of Removal.**—Messrs. C. E. G. Gilbert and Co. have removed to No. 16, Hanway Street, Oxford Street, W.

**Electric Welding.**—*The Practical Engineer* concludes an article on Sir Frederick Bramwell's paper as follows:—"So far the applications have been to work not in competition with ordinary welding smith work, and we are of opinion that electric welders will not compete with ordinary work, as they are entirely inapplicable to the great mass of forge work, and the expense of use puts them outside of applications other than special and peculiar." We congratulate our contemporary on being so plain spoken.

**The "Peral."**—If certain of the Madrid journals are to be believed, it would seem that the submarine boat *Peral* has not turned out a failure after all. We are told that the reason for not building any more vessels after the pattern of the *Peral* is because one of the secret contrivances, appertaining to the submerging mechanism, has been made public by an English journal, while Spaniards were kept in ignorance of all details connected with the invention. The periodical we quote from goes on to say that, so long as six out of the seven especial inventions comprised in the mechanism of the *Peral* remain secret, there is nothing much to lament over, and the Government is adopting a proper measure of reserve in abstaining from further construction until the day when, Spain being at war, these powerful engines of destruction can be made use of against an enemy as novel weapons of offence.

**The Compound-Winding Case.**—The reason why the appeal to the House of Lords has been made may be seen by referring to the report of the Brush Electrical Engineering Company's first annual meeting. Those who have paid royalties for the use of compound-winding will doubtless feel flattered at the consideration which the company deigns to give them, more especially as nothing is recoverable should the appeal be dismissed. But surely, if the statement made by the chairman at the end of his last speech is correct, the manufacturers who have hitherto paid royalties can refuse to do so any longer, even if the company is successful in the House of Lords, on the ground that their dealings were with a previous corporation?

**Railway Telegraph Engineers.**—The Society of Railway Telegraph Engineers is to hold session in the Edinburgh Exhibition on the 16th and 17th of this month. The society is composed of the telegraph superintendents of the different railways. Two important exhibits, illustrating the telegraph, the signalling, and the block systems of two of the leading railway companies, will prove of special interest.

**The Electro-Magnet.**—The Journal of the Society of Arts for September 5th contains the first of the Cantor Lectures by Prof. Silvanus Thompson, D.Sc., B.A., M.I.E.E., delivered January 20th, 1890. The subject treated of is "The Electro-Magnet," and the inventions of Sturgeon, Henry, Roberts, and Joule are described.

**Proposed Electric Tram at Hastings.**—At the last monthly meeting of the Town Council a communication was received from Mr. J. Lees, enquiring whether the Council would entertain a project for a single line electric tramway south of the present parade rails from a point nearly opposite the Palace Hotel and the South Colonnade. The matter was referred to the Council in committee.

**A Well-Known Fact.**—A facetious friend, who noticed that in some of the B.A. papers attributed to certain authors, the mathematical portions were eschewed during the reading, suggests that the tendency on these occasions is merely to general lies. There is nothing new in this.

**Electric Traction in Italy.**—In the course of a few days the electric tram service between Florence and Fiesole will be open to the public. The preliminary trials have been highly satisfactory.

**Electricity in Artillery Practice.**—*Engineering* last week reproduced a very complete description, from the *Revue d'Artillerie*, of Paris, of the Canet system of quick-firing guns, which are equipped with electrical devices for training both in elevation and direction. If we are not much mistaken, the same ideas were carried out some years ago by Mr. Maxim, Mr. Crompton, and others, and although perhaps never put into practical operation, they were experimentally successful.

**Cable Ships.**—The ss. *Westmeath* arrived at her moorings off Messrs. Henley's Telegraph Works at Woolwich on the 8th inst. She is about to load cable for the extension of the Société Française des Télégraphes Sousmarins system in the West Indies. We believe the first section to be laid on this expedition will connect the French Island of Martinique with the town of Paramaribo, in Dutch Guiana. She is expected to leave the river early in October.

The ss. *Silvertown* came to her moorings off the Silvertown Company's Works on the 10th inst. She will take in cable for the West Coast of South America, the Central and South American Telegraph Company having resolved to continue their system southwards, from Lima, the capital of Peru, to Valparaiso, the chief port of Chili, touching *en route* at Iquique, the nitrate port, only. This extension of the Central and South American Company's cables would appear to threaten a serious rivalry to the existing lines along the coast, owned by the West Coast of America Telegraph Company. The *Silvertown* is expected to leave the river about the middle of October.

**The Aluminium Company.**—At the annual ordinary general meeting, held on Tuesday, at Cannon Street Hotel, Mr. Gerald Balfour, M.P., the chairman, said, amongst other things, that when the company was formed, it was expected the discoveries of Mr. Webster and of Mr. Castner, two of the vendors, now upon the board, would enable the price to be reduced from 60s. to 20s. But all their calculations were overthrown by the invention of an electric process for the production of the metal, which brought the cost down to 6s. or 8s. But he was glad to say that, though the metal could not be produced at a lower cost by their present process, yet Mr. Castner and Mr. Webster had discovered new processes of making aluminium and sodium, which, it was hoped, would once more enable them to compete with the electric process as far as the production of aluminium was concerned; while they would, it was hoped, also have a large sale for sodium.

**New Zealand and the Cable Rates.**—The New Zealand Government declines to bear a share of the subsidies and guarantees required by the cable companies in connection with the proposed reduction of the telegraph rates between Australasia and Great Britain, owing to the refusal of the Imperial Government to bear any portion of the responsibility.

**Fatal Gas Explosion.**—Yesterday forenoon a serious gas explosion, attributed to a leakage from a gas engine, occurred at the electro-plate works of Mr. C. H. Worsnop, in Cheapside, Halifax. The explosion almost brought down the building and set it on fire. A young man, named John E. Worsnop, was buried in the *débris* and has not been found, and a young woman, named Hartley, a burnisher, was killed, whilst a labourer was so seriously hurt that he lies in the infirmary in a precarious state.

#### NEW COMPANIES REGISTERED.

**Railway Construction and Maintenance Company of Mexico, Limited.**—Capital, £100,000, in £10 shares. Objects: To construct, maintain, and work railways, tramways, gas and electric lighting works, telegraphs, telephones, or other works. Signatories (with 1 share

each): C. Chabot, Romford, Essex; W. J. Longhurst, 20, Abchurch Lane; R. J. Garwood, 354, York Road, Wandsworth; G. Mannafor, Hendon; H. M. Winears, 15, Crossfield Road, South Hampstead; A. J. Kent, 8, Cross Road, South Wimbledon. The signatories are to appoint the first directors. Qualification: £500 in shares or stock; the company in general meeting will determine remuneration. Registered, 3rd inst., by Messrs. Bircham & Co., 50, Old Broad Street.

**John Smith and Sons, Limited.**—Capital £250,000, in £100 shares. Objects: To acquire the business of wool combers and worsted spinners, carried on by John Smith and Sons, at Field Head Mills, Bradford; to generate electricity, and apply the same for purposes of lighting, or as a motive power; and to supply electric light to any persons willing to purchase, rent, or use the same. Signatories: J. W. Smith, Mrs. Sarah Smith, B. Smith, John Smith, \*J. White, F. White, 1 share each; \*Isaac Smith, 10 shares; all of Bradford. The signatories denoted by an asterisk are the first directors. The company in general meeting will determine remuneration. Registered 4th inst. by Mr. C. Doubble, 14, Serjeant's Inn, Fleet Street.

**London and Western Syndicate, Limited.**—Capital, £10,000, in £1 shares. Objects: To search, prospect and explore countries, districts and places in America, Canada and elsewhere for the discovery of openings for the profitable employment of capital, and to execute and carry out public works of all kinds, including gas, electric light, telephonic, telegraphic and automatic power and other works. Signatories (with 1 share each): N. P. M. Tronson, 8, Drapers' Gardens; B. F. Weeks, 16, St. Helen's Place; R. Leapmann, 124, St. Vincent Street, Glasgow; F. H. Homan, 8, Drapers' Gardens; P. J. Economides, 79, St. Helen's Gardens, W.; G. Allan, M.I.C.E., 10, Austin Friars; W. Curtis Thomson, 10, Throgmorton Avenue. Registered, 8th inst., without special articles, by Robinson & Stannard, 17, Eastcheap.

## OFFICIAL RETURNS OF ELECTRICAL COMPANIES.

**General Electric Company, Limited.**—The annual return of this company, made up to the 2nd inst., was filed on the 5th inst. The nominal capital is £60,000, divided into 7,000 first preference shares, 1,000 second preference shares, and 4,000 ordinary shares of £5 each. 10,505 shares are taken up, and of these 4,000 ordinary and 1,000 second preference are considered as fully paid. Upon 5,505 first preference the full amount has been paid, the calls paid amounting to £26,275, and unpaid to £1,250.

**Pilsen, Joel and General Electric Light Company, Limited.**—A meeting of this company was held on the 5th inst., when an account was given as to the manner in which the winding-up of the company has been conducted and its property disposed of. The notification of the meeting was filed on the same day.

**Tilbury Portland Cement Company, Limited** (manufacturers of concrete and metal telegraph poles, signals, tubes, &c.).—The statutory return of this company, made up to the 12th ult., was filed on the 18th ult. The nominal capital is £25,000, in £5 shares. 2,992 shares have been taken up, and £2 per share has been called. Upon 200 shares the full amount is considered as paid. The calls paid amount to £5,422 10s., and unpaid to £161 10s.

**District Messenger Service and News Company, Limited.**—An agreement of the 6th June (filed 1st inst.), with C. T. Russell, provides for the purchase of the "improvements in electrical signalling apparatus for police service and the like" (provisional protection, No. 6126, granted to R. D. Radcliffe, 22nd April, 1890). Also "Improvements in and relating to printing telegraphs, and to the distribution of news transmitted thereby"

(provisional protection, No. 8031, granted to R. D. Radcliffe on 22nd May, 1890). The purchase consideration is £39,750, payable £15,000 in cash and the balance in fully paid shares. The company will also take over the office of the vendor at 4, Northumberland Avenue, with all instruments, furniture and effects therein at such price as may be determined by a valuer to be appointed by the directors.

An agreement of the 29th ult. (registered 1st inst.) stipulates that the vendor shall not be entitled to require the company to make any payment in respect of the cash portion of the purchase consideration under the principal agreement, except as provided by the following articles. All money received by the company for subscriptions in respect of the first 4,000 shares of the company subscribed for in cash shall be retained for working capital. All moneys received for subscription for shares beyond 4,000, up to the sum of £15,000, to be paid to the vendor. If the full amount be not paid before the 29th August, he will be entitled to require the company to forthwith allot to him or his nominees fully paid ordinary shares, equal to the nominal amount remaining unpaid.

An agreement of 1st Sept. (filed 3rd Sept.) cites that only £1,890 has been paid in cash, and in accordance with the vendor's request the company will allot fully paid shares to the amount of £13,050, being the balance of the £15,000 payable in cash.

**International Okonite Company, Limited.**—The registered office of this company is now situate at 98 and 100, Queen Victoria Street.

## CITY NOTES, REPORTS, MEETINGS, &c.

### The Brush Electrical Engineering Company, Limited.

THE first annual general meeting of the company was held at the Cannon Street Hotel, on Monday, the 8th inst., Lord Thurlow in the chair.

The Chairman, in moving the adoption of the report (printed in our last issue) and accounts to the 30th June, 1890, said that as this was the first opportunity he had had of addressing the shareholders at an annual meeting, he might, perhaps, be pardoned for saying a few words in description of the position of the company, and the financial and other results of the amalgamation. Although at the statutory meeting of the company, held on the 25th November, it was reported that the amalgamation with the Australasian and the Falcon Companies had been satisfactorily carried out, yet, perhaps, at that time the amalgamation existed more or less on paper. It had now been made a reality. As regards the reconstruction of the Anglo-American Brush Electric Light Corporation, there was very little to be said beyond what they knew already. The Brush Company retained its works in the Belvedere Road and other places, in fact, everything it possessed, and, in addition, it had acquired some valuable assets. New shares had been issued to the old shareholders, that was to say, the old shareholders had received new shares in exchange for the old at the agreed upon rate. As regards the Falcon business at Loughboro', Leicestershire, no time had been lost in taking those works over, and about £20,000 had been spent in erecting new shops to enable the company to construct the heavy machines it was now called upon to make. As regards the Australasian Company, the original scheme had been that the company should take over the whole of that business, including patent rights and stores, and issue to them £45,500 in shares and £500 in cash. The negotiations had been very protracted, not owing to any unwillingness of either party, but owing to the difficulty experienced in adjusting some of the assets. They were now satisfactorily concluded, but with a certain modification, namely, that the Brush Company, instead of taking over the stores, floating assets and liabilities, agreed to take over only the patents and the shares in the Melbourne Company, and to issue £31,000 in fully paid up shares to them instead of £41,500. Subsequent negotiations which took place had been owing to the inability of the Australasian Company to give a good title to everything that had been scheduled. They were matters of no material importance, but a certain deduction had had to be made on account of them. The financial result had been that the Brush Company took over the patents and shares of the Melbourne Company for £27,500 in shares, two-fifths ordinary and three-fifths preference. Had it not been for the conciliatory attitude of Mr. Van Tromp, the chairman of that company, and the liquidators, the difficulties in the way of the amalgamation might have been insurmountable, which would have been unfortunate. Negotiations were still on foot with a view to the Brush Company taking over the whole of the Melbourne Company's stores. From

the first the Brush Company had said that they would not take over its assets and liabilities, and that decision had been adhered to. The amalgamation had opened up to the company an enormous field for business, and one which would require very considerable energy on the company's part to do justice to. To obtain a fuller grasp of the position occupied by the company in that part of the world the directors had requested Captain Rowan to come over from Australia to advise them on all points. He came, and lengthy meetings had been held, and every point thoroughly sifted. Finally, satisfactory terms had been made for engaging him for a term of years to look after the company's interests and take charge of its business in Australasia. The final result of the issue of shares had been as follows:—To the Anglo-American Brush Company £156,942 ordinary and 104,628 preference shares; to the Falcon Company £33,305 ordinary and £22,200 preference shares; to the Australasian Company £16,500 ordinary and 11,000 preference. The balance of capital appearing in the report and balance sheet had been raised by subscription, making in all an additional £24,192 in ordinary shares and £164 in preference shares; and after all these transactions the company had only £256 10s. as outstanding arrears. They would, he thought, agree that that was a satisfactory result. Those arrears would, he hoped, very shortly disappear. The £75,000 debentures issued by the new company could, of course, only be so with the consent of the existing debenture-holders of the old Brush Company. That had been obtained; that was to say, those debenture-holders had been induced to convert their debentures or they had been paid off. They had behaved in a very friendly spirit, and the debenture charge on these great properties was very light indeed. Those debenture-holders had agreed to take the new debentures with the exception of £7,900, which had been purchased by the liquidators of the old company, and formed a very valuable security for any shareholder who liked to get 6 per cent. for his money. He thought it more desirable to keep those debentures, and, for his own part, would be prepared to take up some, and he strongly urged the shareholders to absorb them. They would be retained by the directors for a time for that purpose, and there would be no difficulty in disposing of them. As to the general efficiency of the combined works which the company now has: The Brush works in the Belvedere Road were in themselves very perfect, and the Falcon works by themselves were extremely satisfactory for the acquisition of work; but the combination of the two for the carrying on of electrical engineering formed an unrivalled position. The situation of the Falcon works was everything that could be wished as enabling the company to obtain the best and most skilled labour and the cheapest fuel. Moreover, they were on one of the main lines of railway, viz., the Midland, the Loughboro' station of which had sidings actually adjoining the company's works. Taken in conjunction with the Lambeth works, they enable the company to distribute its heavy work and its fine work most satisfactorily. The Falcon works occupied about seven acres of freehold land, or 35,646 square yards. About two-thirds of that space was built upon with the old shops taken over and new ones subsequently erected, leaving unoccupied land of about 12,900 square yards. The lifting power provided at the new works was very extensive and complete. The largest size of machine the company at present turned out was the Victoria-Mordey dynamo, and they had already in course of construction a dozen machines of more than twice that size, that was to say, 30 tons. Of course, very heavy cranes were required, and the foundry was fitted with all that. The company was now able to cope with work of almost any magnitude. As regards expenses and profits: the latter appeared in the balance sheet; they would find that the expenses had slightly increased, but that was unavoidable, if they considered the vast body of work done, the expenses of the amalgamation, and of securing these additional works at Loughboro', &c. The expenses had increased from £11,131 in 1888 to £16,000 in the present year, and he did not think he could hold out very much hope of their being much reduced in the future. The directors would do what they could. There had not been, nor would be, any extravagance or want of care and attention. It was one of the inseparable results of extending business. As regards liquidators' balances, £9,979, he thought the shareholders would make their minds quite easy. No less than £7,900 represented the debentures of the old company which had been purchased by the liquidators, and the balance consisted of sundry small debts and accounts. As regards the litigation with the King-Brown Company, they were bound to take the case to the House of Lords for two reasons—first, because the English court of law had originally decided the case in their favour; and, secondly, to justify their having taken royalties from every manufacturer in Great Britain for some years past. Of all other litigation the company had pretty well washed its hands. Then, as regards their policy in reference to a matter of importance second to no other in the electrical world, viz., the obtaining of provisional orders; the directors had, as a general rule, confined their applications to places in which the company had interests to serve, like Bournemouth, Cardiff, and others more numerous than might be supposed. They had acquired the Bournemouth order, and also one-third of the City lighting. The City had been divided for this purpose into three great districts, and the Brush Company had acquired the central one, which was certainly not second in importance to any of the others. The company had to carry out the work under very favourable conditions, and strict but not impossible terms as to date; in fact, it had still some months before it would be compelled to commence the work. The cost of carrying it out would amount to some £300,000, and it formed a very valuable asset. The company em-

ployed some of the most experienced of the men connected with electrical and engineering work. The latter was almost as important as the former, and no company that did not combine to the utmost experience and knowledge of both could hope to carry out satisfactorily such an order as this. As regards the dividend—the profit and loss account showed a gross profit of £36,698, and after deducting all standing charges there remained a balance of £14,235. Out of that the directors proposed to write off £3,000 on account of property and patents, to apply £625 to reduction of preliminary expenses, and write off £500 on account of a small sum of £1,500 spent, and still being spent, in obtaining provisional orders. That left a balance of £10,426 to be appropriated. Out of that, of course, had to be paid dividends due on preference shares for the six months from February 10th to now, viz., £3,505, an interim dividend of £3,808 6s. 10d. having already been paid. Altogether, then, it was proposed to pay a dividend of £7,313 11s. 4d. on the preference shares, and to carry forward a balance of £2,796 to the next account. It was, perhaps, an act of purism to write off £500 on account of that £1,500 for provisional orders and £3,000 on account of the property account. The shareholders were not compelled to consent to it, and in that case they would have £6,800 available for a dividend on ordinary shares. They could if so disposed appropriate and divide a dividend on the ordinary shares for the past twelve months of 3 per cent., after paying the dividend on the preference shares and the debenture charges and every other legitimate expense, and that without taking into account any profits accruing from the Australasian branch. The directors, however, did not recommend that course, but that it should be appropriated as suggested in the balance-sheet. It was necessary the company should occupy in the future a strong financial position as well as a strong manufacturing one, and no company could do so unless it acted on certain recognised rules, one of which was to write off from the property and patents account as much as it could afford, and also a portion of other charges of an exceptional character. The scheme proposed by the directors was in accordance with sound finance. He did not anticipate their having to raise the £300,000 for the City order—the company would be paid on account as the work progressed—but undoubtedly a work of that magnitude could not be entered upon unless with a certain amount of ready money. They must, therefore, not be surprised if required to raise additional money, and should the event occur, it was essential that their last balance-sheet should appear sound. He moved the adoption of the report and accounts.

Mr. Van Tromp, in seconding, said he could give his assurance that the company was on the high road to being a very great success. He had inspected the works at Loughborough, and he did not hesitate to say that, for the purpose, there were very few premises in England better adapted. They possessed appliances which would enable the company to do everything connected with electrical motive power, from the commonest electrical apparatus to a large electrical car, an engine, or anything. The chairman had omitted, with regard to the Australian transfer, to mention that it comprehended the Cape of Good Hope and India. India he looked upon as a future grand field for electric lighting: it was a country of luxury and wealth, of enormous incomes, a very warm climate, in which electric lighting as against gas must be immensely favoured. Nor had any allusion been made by the noble lord to the company's works in Vienna and Austria-Hungary. The former were carried on at considerable profit, which was gradually increasing. The company had a great future in Vienna. As regards the Hungarian business, from the very latest advices received, it was a positive fact that electric lighting was completely beating the old gas company. It was believed that the whole lighting would shortly be in the hands of the Brush Company, to which very large profits must ultimately accrue. The directors would only be satisfied with giving the shareholders not merely a good but a handsome dividend. Everything was now in the most perfect working order.

Mr. Smart, a shareholder, thought the directors ought to be made acquainted with the feeling of the shareholders with regard to the non-receipt of any dividend for some years past. They had heard exactly the same promises for the future as they had done for some years past; but the result to the shareholders had been very different. The chairman said it was a new company; to the shareholders it was merely a change of name.

The Chairman reminded the speaker that the shareholders were getting a dividend.

Mr. Smart said something like 2 per cent.; a nominal dividend, certainly.

The Chairman said there was a dividend of 6 per cent. per annum on the preference shares.

Mr. Smart was not to be deluded. Like every preference shareholder, he also held a large amount of ordinary stock. Their receipts were really under 2 per cent. They felt greatly disappointed.

Mr. Ward would like to hear the charge of £8,000 for salaries explained. He hoped the directors were alive to the importance of electrical traction, and would be prepared to take the lead. Like other shareholders, he was anxiously looking forward to receiving a dividend on the ordinary shares, but he thought the board had done wisely in making the distribution as they had done.

Another Shareholder asked whether failure of the appeal in the King-Brown case would imply that the company would have to refund the royalties actually received by it.

The Chairman, in reply, said he anticipated a great development in the electrical industry to result from the recent removal by

Parliament of restrictions which had been quite prohibitive, and also from the public having become awake to the advantages which electricity offered. He had omitted to include in his former remarks the relative cost of manufacture in London and in Loughboro'. This as regards price of labour, coal, castings, &c., was very considerably in the company's favour. The £8,000 for salaries included those of the manager, sub-manager, skilled electricians, draughtsmen, managers at Loughboro', Vienna, and in Australia; in fact, a vast number of highly skilled men, and everything except directors' salaries and workmen's wages. The electrical tram car business had been beset with difficulties of various kinds, but it was now emerging from those difficulties, and it was one of the objects the directors had had in view when amalgamating with the Falcon Works, which were so admirably adapted for the manufacture of those cars, and which, moreover, placed the company in actual touch with the present users of horse cars, a great number of which had already been turned out by the Falcon Works. Only the other day the company received an order from the London Road Car Company for 60 busses. The works were also well adapted to the manufacture of electrical launches. The company was making a great many engines at Loughborough. The royalties referred to had been received by the previous company, and whatever might be the decision of the House of Lords, they were not recoverable from the Brush Company. All that would happen would be that the company would receive no more royalties.

The motion was then put, and carried unanimously.

The Chairman also moved to declare a dividend on the preference shares of 6 per cent. per annum for the period from 10th August, 1889, to 30th June, 1890; and that the balance dividend (after payment of an interim dividend on the 1st March last) be paid on the 19th September next.

The motion was agreed to, and, with a vote of thanks to the chairman and directors, the meeting dispersed.

**Commercial Cable Company.**—The transfer books will be closed from September 20th to October 2nd, for the payment of the usual quarterly dividend of  $1\frac{1}{2}$  per cent. on October 1st.

**National Telephone Company.**—The committee of the Stock Exchange has ordered 2,284 additional shares, No. 436,701 to 438,984, to be quoted in the official list.

#### TRAFFIC RECEIPTS.

The Great Northern Telegraph Company, Limited. The receipts for the month of August amounted to £25,000; 1st January—31st August, 1890, £181,000; corresponding months 1889, £178,200; do. 1888, £179,300.

The Western and Brazilian Telegraph Company, Limited. The receipts for the week ending September 5th, after deducting the fifth of the gross receipts payable to the London Platino-Brazilian Telegraph Company, Limited, were £4,500.

### BRITISH ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.—LEEDS, 1890.

#### ELECTRIC LIGHTING AND FIRE INSURANCE RULES.

By WILSON HARTNELL.

(Read before Section G, September 8th, 1890.)

**Introduction.**—Every system of artificial illumination involves some risk from fire. Electric lighting, although it may be the safest of lights, is not exempt from this danger.

Until recent years, insurance companies have given their attention to framing regulations for checking the spread of fire when once it had originated, rather than devising means for preventing an outbreak.

The early inexperience and ignorance of many who undertook electric lighting, and consequent accidents, rendered some guidance and restrictions absolutely necessary for protection against fire. No authority existed. The Society of Telegraph Engineers proposed a few obvious regulations which were accepted by the majority of insurance companies as sufficient. Comparatively recently the Electrical Society have framed a much more elaborate, and an admirable set of suggestions. Meantime the Phoenix and many other fire offices have formulated conflicting rules or their own, which they more or less enforce.

I say advisedly, more or less, because on the one hand, in the absence of any comprehensive and competent system of inspection on the part of the insurance companies, and their different requirements, and, on the other hand, in their desire not to lose business, no standard of excellence is attempted.

Much is left to the conscience or ability of the contractor, which is unjust to those who abide by the best rules.

Large numbers of persons and millions worth of property are affected by these rules.

The object of this paper is to point out much needed amendments.

Such rules should be based on the deductions of experiment and the teaching of experience. They should give the utmost freedom of action and encourage progress. They should contain the minimum that is necessary, and this should be strictly enforced. Above all, these rules should be in accordance with the general principles which regulate all successful engineering constructions. For example, if we consider such familiar but different structures as a locomotive engine, a steamer, a bridge, we shall observe that there is no absolute safety in any one of them. Each has been perfected, not by directing the mind to a particular class of facts, but by a judicious compromise between many conflicting necessities, by giving neither more nor less than a just measure to each requirement, and in each case, all this has had to be done with due economy and limited means. In this spirit, all fire insurance regulations should be framed.

**Conductors.**—In regard to conductors, my first point is to show that any attempt on the part of the insurance companies to determine a fixed current density is useless, vexatious, and scientifically wrong.

For any electric light installation it is necessary to limit the fall of potential in the more distant lights. This can only be done by so limiting the current density that there is not the remotest chance of fire from over-heating of the wires. For example, suppose the fall of potential between the brightest and dimmest lamps were limited to 4 per cent., and the most distant lamp was 75 yards from the dynamo, then the mean current density must not exceed 1,600 amperes per square inch. If the distance be 100 yards, 1,250 amperes per square inch; if 150 yards, 800 amperes, and so on. In any electrical installation in a large building, it is convenient to sub-divide the lights into groups, dependent upon their distance, and to adopt a table of wires and lamps on the several circuits corresponding to these mean distances, and thus secure comparatively uniform brightness. If, however, an arbitrary rule, such as 1,000 amperes per square inch be insisted upon, this rational principle of lighting cannot be adopted. It is, of course, necessary to adopt some limits of currents, but these depend upon the sizes of the wires, as it is easily shown by experiment and reasoning that the larger the cable the less must be the current density. However small the current, the smallness of the wires must be limited. For example, No. 20 S.W.G. is perhaps the smallest size that should be used, for fear of mechanical injury. In mansions, &c., where the first cost of wiring is of less consideration, and where the wires are placed out of sight, No. 16 S.W.G. may be the limit of smallness. Such details are best left to private judgment, but should be stated on the insurance policy.

That wires can be made red hot by electricity, and give rise to fires, was one of the most obvious facts thrust upon the notice of the insurance companies, and apparently almost the only one they could imagine or comprehend. This danger has been greatly magnified. It is, moreover, the danger most easy to absolutely abolish by judiciously arranged cut-outs.

The current required to heat wires has been the subject of many experiments. The most complete results published were those of Mr. W. H. Preece in 1888 and of Mr. A. E. Kennelly in 1889.

**Experiments on Wires.**—The smallest wire used in electric lighting is the twin flexible wire, equal in section to that of No. 22, S.W.G. It usually carries one lamp and consists of 23 strands, six mils. diameter. (Specimen silk and asbestos covered.)

This experiment shows that one strand only suffices to light a 110 volt 16 C.P. lamp requiring about 58 amperes. This pendant of 23 such strands is therefore absolutely safe with one lamp.

The current density in this small filament is 20,500 amperes per square inch.

This filament will carry three such lamps, say 60,000 amperes current density, without being hot enough to burn anything. It becomes dull red hot with five lamps and a current density of about 100,000 amperes per square inch. It must be remembered that the heat increases as the square of the current, so that with five lamps there is five times five, or 25 times as much heat as with one lamp. This is an extreme case of high current density. Another opposite extreme case I recollect was that of a lead-sheathed cable carrying about 400 amperes with a current density under 700, the temperature of which was found to be 135° Fahr. on a cold day. These extreme cases illustrate the absurdity of a fixed current density regulation.

Experimenting further with this small stranded twin wire, it will be seen that it easily carries eight or ten lamps—in fact, that it may be used to supply a 200 C.P. lamp. According to Mr. Kennelly's experiments, No. 22 = 28 mils. will require about 17 amperes to raise the temperature 100 degrees in wood casing. This is about 30 lamps of 16 C.P., 110 volts, or 27,000 amperes per square inch, current density.

It may therefore be pronounced to be absolutely safe with two or three 16 C.P. lamps. The current required to make the insulation smoke is about 30 amperes, or about fifty 16 C.P. lamps. The temperature which a wire attains, through which any steady current is flowing, obviously depends upon the facility with which the heat escapes by conduction, convection, or radiation. So that the current which makes a wire red hot or melts a flexible wire may be more or less. (Exp. a 1,500 C.P. lamp with 35/40 = No. 23.)

The smallest solid wire used in electric lighting is No. 20 = 36 mils., which at 2,000 amperes per square inch would carry one

ampère, say two lamps; but would seldom be used for more than one lamp.

This wire, according to Mr. Kennelly's experiments, will require about 23 ampères in wood casing to raise the temperature  $100^{\circ}$ . It will carry, as here shown experimentally, a 1,500 C.P. lamp, and remain comparatively cool, whilst no less than about 80 lamps or 50 ampères are necessary to destroy it. No 16, at 2,000 ampères to the square inch, would carry six lamps, but is here shown to be comparatively cool with 50 lamps.

I have allowed 40 ampères to flow through such a wire for a long time without much injuring it, equal to 70 lamps, or over 12,000 ampères per square inch; to burn off the insulation 100 ampères, say equal to 170 lamps are required. It is therefore absolutely safe to use 10 such lamps, which cause less than  $\frac{1}{100}$ th the heat to set it on fire.

#### SUNDRY EXPERIMENTS.

No. 18 destroyed with 70 ampères.

7/20 insulation melted with 110 ampères.

I have observed 19/16s carrying 180 ampères for hours—about 2,900 ampères current density. It becomes warm—according to Mr. Kennelly's experiment the temperature would be raised some 40 degrees.

The scientific rule is that of the Institute of Electrical Engineers, that the wire is to be at least of such size that double the current would not raise the temperature  $150^{\circ}$ . This limit for an initial temperature of  $75^{\circ}$ , calculated from Mr. Kennelly's formulae gives  $c = 560 d^{\frac{2}{3}}$ , and might well be adopted by the insurance companies.

These experiments on the smaller wires used in electric lighting, made not only with a current meter, but with the lamps before our eyes, have demonstrated that there is not the most remote danger of fire with the currents ordinarily used. That on the smallest wire even 10,000 ampères current density would be safe (as safe as 500 current density on mains for 400 ampères), and that for insurance companies to fix a current density, is useless, vexatious and scientifically wrong.

*Fusible Cut-outs.*—Fusible cut-outs seem to be regarded with some mistrust. The point I desire to establish is that by their means the mains and branches may be absolutely protected from danger by fire.

The highest current will be required to melt a cut-out when it is short, and itself and connection cold—when it is longer or covered up, and heated gradually, a lower temperature melts it.

A sudden rush of about twice the current may pass through, melting the cut-outs explosively.

#### *Experiment of Cut-out melting by Degrees, and Sudden Rush.*

A copper wire will likewise take more than double a dangerous current without harm in a momentary rush. On one occasion I observed a short circuit through a No. 16 wire, throw off a magnetic cut-out supposed to be set at 350 ampères, without damaging the insulation of the wire.

The first point to notice is that the fusible wire melts at less current than the copper wire gets damaged.

The next point is to prove experimentally that wires are efficiently protected by fusible wires of the same diameter; and this is the only point that insurance companies need trouble about. So long as wires are efficiently guarded, it is no business of theirs what the working current may be.

It may be experimentally shown that even larger cut-out wires would protect copper.

But this is bad practice since, in most cases, much smaller cut-out wires can be used—especially in the larger mains.

There is some danger of the flash from a sudden rush lighting inflammable dust, if so fixed that such dust can settle on them.

The subject of the construction and position of cut-outs is most important, but would require a paper to itself.

Experience has led me to regard good cut-outs properly fixed and wired with almost implicit confidence as protecting the wire.

*Contacts.*—In an experience extending over seven years, all the dangers of fire have proceeded from imperfect contacts (with two exceptions). In two cases the wires were cut in two by carpenters, not concerned with electric lighting. In one case a fire arose from the slackening of a binding screw through shrinkage of wood. The resistance of a well-scraped contact is considerable, but loose screwed contacts get hot with even 5 ampère currents. Broken wires with ends in contact are sure to set the insulation on fire through sparking. Insufficient area of contacts leads to heating. Cut-out wire requires specially good contacts to prevent melting at their ends from this cause.

#### *Experiments on Contacts.*

Cut-outs are no protection against heating and sparking from imperfect or broken contacts. The following rules are useful:—Avoid screwed joints as much as possible; screw them up tight, with good areas of contact; on no account allow them out of sight. Solder every connection as far as conveniently practicable.

All sharp kinds in solid wires to be cut out, not straightened. Use standard wires as far as possible. Put no very small wires out of sight.

Intelligent and conscientious workmen are desirable to obviate this contact danger.

Cut-outs must be placed in conveniently accessible positions. Short circuits readily occur at the lamp-holders chiefly from meddlesome curiosity, but are almost impossible elsewhere if the wires are properly fixed and let alone, so that the risk of moving the cut-out from the root of the branch is about zero. It is easy to make this assumed risk absolutely zero, for if the cut-outs be no larger than the branches they protect, each wire has a second protection in the cut-out of the next superior branch.

Experience with cut-outs shows that if only a small margin be allowed, they are after a while liable to melt with the working current, apparently from deterioration of contacts and gradual accumulation of heat. In fact, cut-outs seem only too ready to melt, and are absolutely trustworthy to prevent fire from excess of current.

The insulation required for telegraphic work and that for electric lighting work are not necessarily the same. In the former the wires extend for hundreds of miles, and the storage of energy in the batteries is both costly and limited. In electric lighting the wires are short and power abundant, most engines could easily be improved from 10 to 15 per cent., and the owners will not incur the small expense, so that 1 or 2 per cent. leakage of electricity, which would be considered enormous, is almost of no consequence from a prime mover point of view (so to speak).

The chief object of electric light insulation is safety; and this safety, like that of a steam boiler, should be not for one or two years, but for as many years as possible. Durability is, in my opinion, of far more consequence than high insulation. I therefore consider naked wires on insulators (where practicable) the best of insulation, and I regret to say that I look upon vulcanised India-rubber with some distrust. Exposed to the air, vulcanised rubber often cracks, and more or less perishes in a few years. It may be that when held together and protected from the air, as it is in the cable, it may last for say 20 years or more. For damp places, vulcanised rubber is indispensable, or some waterproof insulation.

Recollecting that all work has to be done with limited means, and at some risk, it is very important to have clearly defined what wires will pass the insurance companies, and under what circumstances, and at what premiums.

Here are specimens of wires by two London and two Manchester firms:—

1. Single rubber-covered wires, which appears to me the least insulation desirable for wires in casings.
2. Double rubber-covered wires.
3. Light vulcanised rubber-covered wires.

The prices of similar qualities by different makers are much the same. But the price of single rubber-covered is 20 per cent. less than that of double rubber-covered, and light vulcanised about 40 per cent. more than double rubber-covered.

Any of these wires when dry, the insulation per square foot in area is very great, and a low insulation means local faults, perhaps one local fault which may be a source of danger. On the other hand, the insulation is very much lowered by damp weather.

To overhaul an installation so thoroughly as to trace and eliminate every slight fault would involve far more labour than is ever likely to be taken. Hence the greatest protection, in my opinion, is to be obtained by using good material and good workmanship throughout, and not trust to merely insulation tests only.

A bad job may test well, and *vice versa*.

It is not fair to demand very high insulation tests for wires without also specifying the quality of insulation. Because a single rubber wire, or possibly a wire innocent of India-rubber, may test as well as vulcanised wire in dry weather.

It must also be remembered that although the insulation of the bases of the switches and cut-outs is high, yet in the aggregate (if the switches, &c., be numerous), they will reduce considerably the total insulation. If the test be between the positive and negative wires, the lamp fittings will greatly reduce this, so also that of the twin wires for the pendants, the insulation of which I have known to vary from 120 megohms per milé when dry to 48,000 ohms per milé when soaked in water and drained.

I find the ordinary twin flexible asbestos, covered, to be 10 to 20 megohms per milé.

Thus, for testing to be fair, it must be stated how the tests are to be made.

*Casings.*—The casings are mechanically useful to protect and support the wires; they have the disadvantage, putting it from an insurance point of view, of concealing it.

They no doubt assist the insulation.

The space between the grooves has now been reduced to a reasonable width, at the same time it seems unreasonable to put all qualities of wire on the same footing. It seems to have been forgotten, curiously, that when switch wires, say positive, are laid on a positive wire and switched off, they become negative. The possible current through them is no doubt limited to that which would go through the lamps.

Seeing how much this practice is followed, and its convenience, it is another argument for the use of good wire, with which under such circumstances accidents are hardly conceivable.

The use of varnishing casing seems very doubtful; if the place be not damp it can be of no service; if it be damp then a wire that will stand damp ought to be used.

Non-inflammable paints, to prevent the casing taking fire, seem

to me ridiculous. There can be no remote risk of fire in the casing, if the work be properly done.

Of switches very little need be said on the main sections, double pole switches are convenient, but on the branches double pole switches and double pole cut-outs, by the extra expense and complication they would entail, would more than defeat any imaginary advantage urged by their advocates.

*Equity of Rules.*—The grievance of ill-framed and conflicting fire insurance rules is not only that they interfere with the carrying out of the work in the manner best suited to the circumstances, but there is difficulty in knowing what is required, by insisting, or appearing to insist, on a certain class of material, &c., in one case, and passing very different things in another; there is a further difficulty in not knowing what they will pass.

Those who require the electric light, and know nothing of the matter, are still further bewildered, and are apt to accept the work which is the least expensive, so that the insurance companies defeat the professed object.

It appears, from some recent correspondence in the *London Times*, that of 33 offices, ten offices use the Phoenix rules, ten others have their own special rules, seven deal with each risk as it arises, six use the Institution rules.

In conclusion, I would most strongly urge that the rules of the Institution of Electrical Engineers, with perhaps a few additions, be accepted by all the fire insurances.

ALTERNATING VERSUS CONTINUOUS CURRENTS IN  
RELATION TO THE HUMAN BODY.

By H. NEWMAN LAWRENCE, M.I.E.E., and ARTHUR HARRIES, M.D.

THE present paper is supplementary to a preliminary paper on the same subject read before the Institution of Electrical Engineers on the 27th March, 1890.

In that paper it was stated (*Soc. Journal*, Vol. 86, 1890), that "our experiments have not been made with the powerful currents dealt with in electric lighting and distribution of power," and this admission together with the difficulties inseparable from the accurate measurement of alternating coil currents are points in connection with our paper which have given rise to much discussion in the electrical and other journals.

In the present instance, however, we have endeavoured as far as possible to obviate criticism on these grounds.

1. By using currents directly from lighting circuits—both alternating and continuous.

2. By using currents directly from a dynamo whose rate of alternation could be accurately ascertained.

3. By using currents of high E.M.F.

4. By using an instrument for the measurement of alternating currents, whose accuracy at the reading of our former paper was theoretically questioned by one or two speakers, but which has since been tested and proved to give correct readings by an eminent practical electrician (see page of *Soc. Journal*, Vol. 86, 1890), thus confirming the accuracy of the readings formerly recorded by the instrument, as well as those which are contained in our present paper.

Another practical point to which special attention has been given in this paper is that our experiments have been made chiefly with the skin in a state of nature, so that the conditions of experiment as nearly as possible resemble those which might be expected to exist under accidental circumstances, that is to say under circumstances when contact with the conductors was unexpected and therefore unprovided for.

With so much brief preface, we proceed to give in detail the results of several series of observations made under the conditions explained at each step.

RESISTANCE.

In dealing with the resistance of the human body many difficulties present themselves and render it by no means easy to arrive at definite data thereon. The complicated structure of the body at once prohibits any attempt to regard it as an ordinary inanimate conductor. Several methods have been tried or suggested. The Wheatstone bridge method which we previously adopted, was shown to be inaccurate by Mr. Otto T. Blathy, in the *Electrician*, of April 25th, 1890, and the unsatisfactory nature of comparisons made between resistance measurements taken with the E.M.F. of a few battery cells and those likely to result from the use of an E.M.F., such as is common in light and power circuits has been pointed out by several of our critics.

We have, therefore, thought it best to obtain our resistance measurements by passing the current direct from a light circuit through two or more bodies in series, and then, by noting the current strength passed and the E.M.F. used to pass it, to calculate the resultant resistance.

For this purpose we used in the first case dynamo generated continuous current taken from the lamp leads at the Institute of Medical Electricity, which is supplied by the St. James's and Pall Mall Electric Light Company. Having disconnected a lamp the voltage was tested, and found by a Cardew voltmeter to be 104. We then connected up two metal electrodes of 45 square centimetres area each, which could be grasped in the hand, putting in series therewith only a milliamperè meter having 755 ohms resistance and a key. Two persons joined hands, and each grasped one of the electrodes with his free hand. Circuit was then completed and the reading taken.

The results are set forth in the following tables:—

TABLE A.—RESISTANCE TO CONTINUOUS CURRENT.

Group.	E.M.F. in volts.	Current strength in M.A.	Total R.	R. of milli-ampère meter in ohms.	Resultant R. of each person.
1, two persons	104	7.5	13,866	755	6,555
2 "	"	5.75	18,086	"	8,666
3 "	"	7.25	14,345	"	6,795
4 "	"	9.25	11,243	"	5,244
5 "	"	9.5	10,947	"	5,096
6 "	"	8.0	13,000	"	6,122
7 "	"	10.0	10,400	"	4,822

Average 6,185 ohms.

In the second case we used a dynamo generated alternating current, taken from a Siemens dynamo at the School of Electrical Engineering, Hanover Square, which was kindly placed at our disposal by the managers (Mr. Wm. Lant Carpenter and Mons. Leon Drügan). The arrangements for connection were exactly the same as those described above for the continuous current, except that groups of four and five persons joined hands instead of only two. The same Cardew voltmeter, the same milliamperè meter, the same electrodes were used.

The voltage varied from 115 to 137 and the alternations from 60 to 75 per second.

TABLE B.—RESISTANCE TO ALTERNATING CURRENTS.

Group.	E.M.F. in volts.	Current strength in M.A.	Total R.	R. of Gal.	Resultant R. of each person.
1, five persons	115	4	28,750	755	5,599
2 "	120	5	24,000	"	4,649
3 "	123	7	17,571	"	3,363
4 "	124	7	17,714	"	3,391
5 "	124	6	20,666	"	3,982
6, four persons	123	8	15,375	"	3,655
7 "	137	9.5	14,421	"	3,416

Average 4,008.

These observations show results widely differing from those obtained by other methods and indicate that while under these conditions the R. to the two forms of current more nearly approximate to one another, yet that to continuous current is still considerably greater than that to alternating. It is interesting to note that the average R. to alternating current obtained by this method closely corresponds to that obtained by Mr. Blathy and mentioned in his letter above referred to. He makes it from 4,000 to 5,000 ohms, and our results show an average of 4,008 ohms. We may state then in round figures that we find the resistance of the human body under the conditions named to continuous current to be 1.5 times that to alternating current.

We next endeavoured to find how far variations of the contact area would effect the result and obtained the following readings:—

TABLE C.

VARIATIONS IN CURRENT DUE TO ALTERATIONS IN CONTACT AREA  
(E.M.F. being constant.)

Continuous dynamo current at 104 volts.

Total contact area in square centimetres. (Two electrodes, each having same area, one being grasped in each hand.)		Current strength in milliamperes.				
90.0	...	Sub. 1 10.9	Sub. 2 10.0	Sub. 3 10.0	Sub. 4 10.0	Average. 10.0
45.0	...	7.25	5.25	7.0	5.25	6.19
22.5	...	6.0	4.75	5.75	...	5.5
9.0	Electrodes held by thumb and finger only.	5.75	3.25	4.0	...	4.3

From this it appears that in round numbers:—

A reduction in the cont. area of 50 per cent. reduces the current strength by 40 per cent.; a reduction in the cont. area of 75 per cent. reduces the current strength by 45 per cent.; a reduction in the cont. area of 90 per cent. reduces the current strength by 60 per cent.

It is manifest that to arrive at anything like a definite law on the subject a great number of readings must be taken, but we think the above results form a useful indication of the important bearing contact area has in determining the seriousness, or otherwise, of accidents in light and power circuits.

SENSATION.

In this part of our paper we propose to compare the results obtained when electrodes connected respectively with dynamo-generated continuous currents and dynamo-generated alternating

current are brought into and kept in contact for an appreciable time with the human skin in a natural state, that is to say, in the state normal to the person experimented upon at the time of testing. In order that this series might be complete, it would possibly have been better to give barometric, thermometric and hygrometric readings, of which we have taken many, but these data belong rather to a complicated side issue and do not affect the main question, to which this paper must necessarily be confined, so we have considered it best to omit them altogether, taking it that the subjects experimented on were in an average condition of health at the time, and that the atmospheric conditions were more or less like those to be expected in a climate similar to that of England.

The results are tabulated as follows :—

TABLE D.

Conditions.—Metal handle electrodes grasped in the hands (surface area 45 sq. c. each) in connection with dynamo-generated continuous current, taken from lamp leads, as before mentioned (Table A.), E.M.F. 104 v., by Cardew's voltmeter.

Subject.	Discomfort point.		Fixation point.	
1	...	18 ma.	...	not any.
2	...	15 ma.	...	not any.
3	...	20 ma.	...	not any.
4	...	22 ma.	...	not any.
5	...	15 ma.	...	not any.
6	...	20 ma.	...	not any.
	Average	18.3 ma.	Average	

In each instance, burning sensation under the electrodes became unbearable after about 30 seconds; this was the only objectionable feature, though electrolytic action was sufficiently marked to induce slight blistering in two of the cases. We have to call special attention to the fact that in no case was muscular fixation, or any sensation approximating thereto, reached with the continuous current, nor have we at present any reason to suppose such a result possible.

TABLE E.

Conditions.—Metal handle electrodes grasped in the hands (surface area 45 sq. c. each).  
Alternating current from Siemens's dynamo. E.M.F. 110 v. by Cardew's voltmeter. No. of alternations per second, 23.

Subject.	Current strength.			
	Discomfort point.		Fixation point.	
1	...	30 m.a.	...	60 m.a.
2	...	35 "	...	7.25 "
3	...	4.5 "	...	6.5 "
4	...	3.5 "	...	8.5 "
5	...	40 "	...	7.25 "
	Average	3.70	Average	7.10

TABLE F.

Alternating current from same dynamo as last table.  
Electrodes, as last table.

	Average 4 15	Average 7 90

In Table E, it will be observed that the average discomfort point is 3.7, the average point of muscular fixation 7.10.  
In Table F, the average discomfort point is 4.15, the average fixation point 7.90.  
The mean of the two sets being 3.9 for discomfort point, and 7.5 for fixation point.  
We wish to differentiate clearly between what we have termed discomfort point in connection with both varieties of current, and that which we have called the point of muscular fixation, which we have only been able to discover in experiments with the alternating current. This is the more necessary,

because herein lies one of the great differences in the danger of accidental contact with the two systems respectively.

To put it plainly, we have found no point at which it is impossible to release personal contact with a continuous current circuit, while it is easy with a comparatively low current strength to find a limit beyond which it becomes a physical impossibility to disengage oneself from contact with the alternating current circuit.

A little consideration will show that this cannot be too strongly emphasised, for while with the one, personal effort will suffice to release the sufferer, with the other the agency of a second person must be called into play before the dangerous action of the current can be stopped.

Many of the critics of our former paper appear to have failed to recognise this most important distinction, and to have regarded muscular fixation as synonymous with discomfort point.

Tables E and F were constructed from observations made on the same patients in the same order with the same machine, though with an interval of two days; in the first table the E.M.F. was greater (110 v.) and the rate of alternation less (23 per second) than in the second table, when the E.M.F. was 85 v., while the alternations were 68 per second.

In Table E fixation needed nearly twice as much current strength as discomfort, and in Table F the same sort of relation obtains, though in the latter instance the alternations were just three times as frequent.

During the discussion on the paper at the Electrical Engineers, on March 27th, Dr. Harries, in his reply, stated that "the more rapid the alternations the more nearly did the conditions resemble those present with continuous current as regards sensation." Putting aside for the moment the difference of E.M.F. in the two sets of experiments (25 volts) a comparison of Tables E F will fully bear out this statement, for we find that both average discomfort points and average fixation points are higher, though the alternations are so much more frequent in Table F.

It may not be out of place here to note that observations made with a Wheatstone's transmitter in another series of experiments, at about the same time, showed that a higher rate of alternations, with same E.M.F. and current strength, reduced the sensation.

It is conceivable and probable that nerve impulses travel as waves at a given average rate of speed (90 feet per second, Helmholtz). But sensations may follow one another so rapidly and so irregularly that one set of waves may impinge upon and modify the next preceding set, thus altering the total effect which would be produced upon cortical centres by a given number of sensations in a given time.

Alternations may be so rapid and irregular that these conditions are present in such wise, that the total effect of a series of shocks given at a certain rate of speed is less than the total effect of a similar number of shocks given at a lower rate of speed.

And it is only in this way that we are able to account for the power to bear larger current strength at a high rate of alternation, i.e., when the rapidity is over 50 or so per second.

SHOCK.

With continuous current shocks (sudden make or break), from dynamo-generated continuous lighting circuit with a current strength of 10 to 20 ma., the sensation was that of a sudden jerk, followed by feeling of heat at the points of contact with the electrodes, increasing until the sensation became unbearable. The make jerk was distinctly more marked and more unpleasant than the break jerk, though the latter was followed by an increase in the sensation of heat in the neighbourhood of the points of contact—the increase persisting for two or more seconds after contact was broken.

Shocks of alternating current from Siemens's dynamo-generated alternating circuit were also taken by the subjects concerned in Tables A, B, C, &c. A tingling sensation was felt, which rapidly increased to muscular contraction, becoming more and more unpleasant, and accompanied by a sensation of heat in the neighbourhood of the electrodes, though not immediately under the site of contact as in the case of the continuous current.

It was noticed that the maximum effect was not immediately felt, an increase being apparent for one or two seconds, the hands being still in contact with the electrodes. This effect was most apparent with small currents (2 to 3 ma.). As the current strength increased the maximum effect was more rapidly produced.

When 8 ma. were passed the effect seemed immediate. Considerable heating of the parts in contact with the electrodes, and of contiguous parts, was noted on both make and break shocks. This continued to invade adjacent parts during the period of continued closure of the circuit, and the general effect included muscular fixation in most of the subjects experimented on.

In our previous paper we concluded by deducing a danger ratio. This showed the danger of serious consequences on contact with the alternating current to be 41.5 times greater than that to continuous currents. So high a ratio was thought by many to be excessive, and the more recent experiments now set forth prove it to be so, if we calculate it on exactly the same lines as before. We find, however, that there are other factors which should be included in calculating the danger ratio, in addition to those used in the former paper, viz., "Differences in Resistance and Sensation." The difference in resistance obtained by the method we have now adopted and set forth in Tables A and B is 1.5 instead of 8.3, as obtained by the former method. The difference in sensation set forth in Tables D and E, on the other hand, is 4.7, or only 0.3 less than that obtained previously. This would give a danger ratio of 7.0. Such a ratio, though far below that obtained with small battery and coil currents, would be sufficiently serious to demand

very careful attention from electrical engineers, if it represented the whole state of the case; but it does not (as mentioned above) cover the whole ground, for we have also to consider two other factors, viz., difference in initial shock and difference in continued contact. On these two heads comparative values cannot be given. As regards initial shock, in which the time period of contact is a minimum, we have made many tests on various individuals, who one and all declare that the initial shock of alternating current of a certain strength is far worse to bear than the initial shock of continuous current of the same strength. This, from the nature of the experiments, can only be tested with small currents, and it is conceivable that with large currents such marked differences may not be observable, the time factor being left out of consideration. The second, however (continued contact) is a matter of far greater importance, as we have already pointed out in discussing muscular fixation. The time period of contact being appreciable with continuous current, we have no muscular fixation, and the subject of accident would be able to release himself. On the other hand, an appreciable time of contact being made with an alternating current circuit, the subject would be absolutely fixed *in situ* until released by extraneous aid, being exposed during the whole time to the full effect of the current passing through him. Further than this, the act of muscular contraction might, and probably would, increase the contact area, and so increase the current allowed to pass.

When, therefore, we take these last-named factors into account, it is manifest that the danger ratio of 41.5 to 1, named in our former paper, is by no means too high. We do not now name another figure, because it appears to us impossible to express in terms that could be used for calculation the differences in initial shock and in continued contact.

It may perhaps be expected that we should make some reference to the quantity of current which constitutes a fatal dose, but this can only be arrived at by careful observation of all the electrical conditions prevailing at fatal accidents or executions.

The difficulty of obtaining such information is generally very great as regards accidents, but surely not as regards executions. That the authorities in charge of Kemmler's execution failed to take measurements of the E.M.F. and current strength used, is almost incredible, and in view of the fact that they possessed so excellent an opportunity, such neglect seems quite inexcusable.

For some time past, we have been hoping that some information in this direction would be forthcoming, but the article by Mr. C. Huntley in the *Electrical World*, reproduced in the *ELECTRICAL REVIEW* for September 5th, 1890, appears to be conclusive, for it says, "No data of either the electrical or mechanical apparatus were taken."

Mr. Parry in his recent articles in American electrical papers, arrives at the conclusion that one ampère is an undoubtedly fatal current, provided it actually passes through the victim. This estimate we see no reason to differ from, though we hardly think sufficient evidence has been obtained on which to base definite conclusions.

We will now briefly summarise our conclusions, and in doing so desire to draw attention to the fact that they are based upon certain conditions, and, while we believe them to be sufficiently accurate and reliable under these conditions, we in no sense claim them as true under all conditions.

#### CONCLUSIONS.

A. When the human body, with the skin in its normal unmoistened condition, comes into contact for an appreciable time with bare metal conductors of a dynamo-generated continuous current passing at 100 volts in such a way that the current passes from hand to hand, and the total contact area is about 90 square centimetres.

1. A current of about 0.016 ampère will pass through it.
2. This current can be borne without discomfort for 15 to 30 seconds.
3. After about 30 seconds unpleasant burning sensations become marked and quickly increase.
4. The subject is perfectly able to release himself at will during any portion of the time of contact.

B. When the human body comes into contact with dynamo-generated alternating currents, alternating at about 60 to 70 per second under the same conditions as above.

1. A current of about 0.025 ampère will pass through it.
2. This current is six times greater than that which produces discomfort.
3. Instantly the subject is fixed by violent muscular contraction and suffers great pain.
4. The subject is utterly unable to release himself, but remains exposed to the full rigour of all the current that may be passing.

C. When circuit from electric light or power conductors is accidentally completed through the human body, the danger of serious consequences is many times greater when alternating than when continuous currents are passing at equal voltage, and this is still to a large extent true if the voltage of the continuous current be double that of the alternating.

D. 1. With both forms of current a reduction of contact area materially reduces the amount of current strength that passes.

2. With the alternating current, if the rate of alternation be reduced below 50 per second, the sensations of pain accompanying muscular fixation will be increased, while if the rate of alternation be increased, the pain will be diminished.

Finally, we would remind those gentlemen who so commonly speak as if voltage were the chief or only factor in the danger of accidental contact, that current strength is the important item, and

that according to Ohm's law current strength is dependent not only upon E.M.F., but upon the total resistance in circuit at the time of accidental contact.

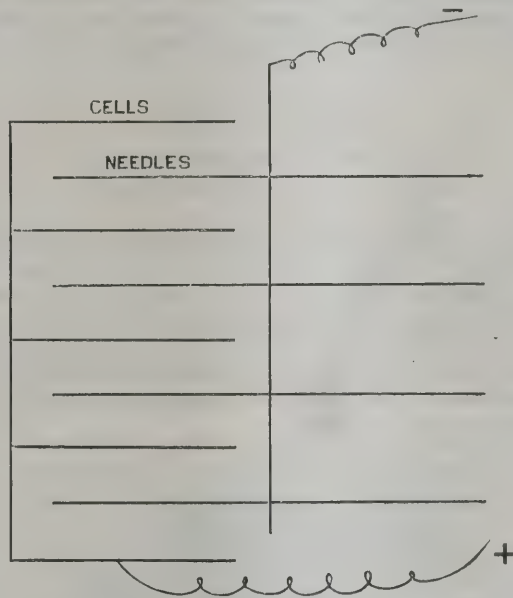

To make statements based upon voltage only, such as newspaper reports of a recent execution have contained, is not only distinctly misleading, but calculated to induce the uninitiated to form erroneous conclusions.

#### ON AN ILLUSTRATION OF CONTACT ELECTRICITY PRESENTED BY THE MULTICELLULAR ELECTRO- METER.

By Sir WM. THOMSON.

(Read before Section A, September 4th, 1890.)

CONTACT electricity of strong metals absolutely removed from possibility of chemical action is a subject which was formerly much discussed, but now the fact of that kind of action is thoroughly admitted, and most of the natural history of the subject is pretty well known. I have not to-day to add to the knowledge of the subject, but merely to remark that it brings out a very curious feature in electrostatic instruments, in illustrating its application to this instrument of contact electricity. The metals in question are brass and aluminium. I am sorry I cannot show you the interior of the instrument just now, but a sketch will probably make it understood. The instrument consists in a multicellular electrometer. In its working it is a number of cells, as the designation indicates, with a needle, or a number of needles, moving under the influence of these cells. There are 20 cells, one over the other, and we will represent this in section.

There are 10 cells acting on one set of ends and 10 at the other. The needles are mounted one above the other on a stem, which hangs by a fine platino-iridium wire. The principle is simply this—the needle is connected through its fine wire with the outside case of the instrument, which is one of the metals between which the difference of potential has to be measured. The other metal is the cells—this pile of cells and the other pile of cells are metallically connected. They are insulated from the outer case of the instrument, and we have a binding screw here connected metallically with the cells, and insulated from the case of the instrument we have another binding screw. The instrument is adapted to measure difference of potential between these two metals. It is analogous to the quadrant electrometer with its needles and quadrants used as two bodies, the needle connected with the case of the instrument. In the quadrant electrometer contact electricity was illustrated by making the two pairs of quadrants, say, of zinc and copper. I have noted a very different manifestation of contact electricity presented by this form of electrometer. Let us suppose that the needles and the cells are maintained at a difference of potential of, say, 100 volts, this instrument before you is adapted to work at potentials of from 60 to 120 volts. If the needles were polished aluminium and the cells polished aluminium, we should have none of the difference due to contact electricity. You get apparently 100 and  $\frac{1}{10}$ ths or 100 $\frac{1}{10}$ , when the needles are positive and the cells negative; on the other hand, when the needles are negative and the cells positive, you get 99 $\frac{1}{10}$ , the mean being correctly 100 volts. I anticipated this when the instrument was first made, but our first trials of all first instruments within the year of preparation showed such effect to a degree so little that it could barely be perceived. You could barely see  $\frac{1}{10}$ th of a volt difference. We made more than a year ago a great many careful experiments, and never found more than  $\frac{1}{10}$ th of a volt. Quite lately my attention was recalled to this by my former assistant, Mr. Rennie, now of the Board of Trade testing laboratory which has lately been established under the superintendence of Major Cardew. He found, with a new instrument recently supplied to that laboratory, a larger difference of just about the

amount we originally expected. I have tried new instruments since, and found it much greater than in the earlier trial instruments. The explanation is, that in the original instruments that were made for trial, with pieces of metal that had been tossed about in the laboratory, and with needles and plates unpolished, the condition of surface was not such as to give the proper difference. But in the finished instruments, with a high polish a definite difference of this kind, much greater than in the original trial instruments, was obtained. I received a letter this morning from Mr. Rennie about experiments on an electrometer at the Board of Trade.

In the course of these experiments at the Board of Trade, extending over a month or six weeks, and made at frequent intervals, there were doubled differences amounting from '5 to '6. There was evidence of a slight decrease in the error, and it is not at all improbable that in time this error may diminish when the initial state of polish may have become toned down. I made one experiment of that kind, subjecting an instrument, just as it stood, both cells and needles, to damping by vapour of water; but the result was not to diminish the difference, but rather to augment it. But exceedingly little change takes place. The explanation is, of course, that polished aluminium is positive to brass, just as zinc is positive to brass, and the effect is of the same kind as would be observed if we had zinc needles and copper cells, the form of contact electricity with which we are most familiar. Let us suppose, instead of being connected to a battery, a metallic connection is made between the cells and the needles; then we shall have a simple contact difference between aluminium and brass. A direct experiment on the force due to that would show no result. Let us say  $\frac{1}{2}$ -volt is the difference.

The force due to this difference when the terminals are metallically connected bears to the force due to it, when a difference of 100 volts is maintained between them, the ratio of  $(\frac{1}{2})^2$  to  $(100 + \frac{1}{2})^2 - 100^2$ , or, approximately, 1 to 800.

#### SECONDARY CELLS.

By W. J. S. BARBER STARKEY.

(Read before Section G, September 8th, 1890.)

I SHALL only try to give a few of my personal experiences with secondary cells without attempting to go into their theory or construction, and I do this more in the hope that it may lead to some interesting discussion, than for any value which may be attached to my experiences. Soon after the introduction of M. Faure's cells into this country I was fortunate enough to become possessed of one, which for a time gave excellent results, but it so happened I had to go away from home for six months, and on my return I found the cell would no longer work satisfactorily, and had become very inefficient.

To find out the cause of this I removed the plates from their felt envelopes, and found that they were partially covered with a white hard sulphate of lead, which I was unable again to reduce; I also found that it had eaten into the supporting plates, and that there was a thin film of white sulphate between these plates and the active material, which practically acted as a non-conductor. This seemed to me such a serious defect that I determined if possible to find out a remedy, and, after numberless ineffectual attempts, I at last found out that if a small quantity of carbonate of soda was added to the dilute acid, it not only allowed the existing sulphate to be again reduced, but it also prevented the formation in future of the hard white intractable sulphate, even if the cells were allowed to stand idle for any length of time. I have allowed plates to remain idle in this solution for more than 18 months, without the slightest trace of white sulphate appearing. Five years ago next Christmas, a small installation consisting of twenty-two E.P.S. 350 ampere-hour cells was fitted up for me, and it so happened that the dilute acid was by mistake put into the accumulators a considerable time before the engine was ready to run, by which time the plates showed signs of sulphating, and as I had only a small current of 10 amperes at my disposal, I was not able again to bring the plates to their proper state, and the sulphating became worse and worse, till all the plates presented a dull grey appearance. I showed them to several electrical experts, and the opinion was that they were ruined, and the only suggestion was that I should pass a heavy current for a long time through the cells. This I was unable to do with the power at my disposal, but I passed a current of 10 amperes continuously through them for a week without the slightest apparent results. Seeing this treatment was hopeless, I then determined to try the carbonate of soda which I had used on a small scale some years previously on the Faure cell. I was told that I should probably ruin the cells, so I began cautiously. Into one cell out of the twenty-two I put a small quantity of carbonate of soda (ordinary washing soda), and I then went on charging as before, and before many hours had elapsed I was delighted to see that the plates in the cell, to which carbonate of soda had been added, were beginning to assume their proper appearance, the positive plates becoming a very dark brown peroxide, and the negative plates a clear metallic lead, which was a great contrast to the uniform dull grey appearance of all the plates in the other cells. As soon as I was convinced that the treatment with carbonate of soda was satisfactory, I added it to all the other cells, with the result that in a short time every trace of the formerly intractable white sulphate disappeared, and the cells presented a beautiful appearance. It is now nearly five years since the cells were thus treated, and

they have never since shown signs of sulphating, and are apparently in as good condition now as when new. I was so much impressed with the use of carbonate of soda to prevent sulphating of the plates, that I brought the matter before Mr. Preece, and he very kindly came to look at the cells, and afterwards carried out a most careful series of experiments to determine the value or otherwise of using sulphate of soda in secondary cells. The results of these experiments are, I believe, well known, and have been published, and the exact amount of carbonate of soda which it is desirable to use has been determined: it is only necessary to use a very small quantity to effect the desired purpose. If much is used it is of no advantage, and may tend to cause scaling of the plates. Now that it is no longer necessary to pass a heavy current through cells, to prevent sulphating, it appears to me that it would be much more satisfactory to use larger cells for stationary work, and both charge and discharge them at a considerably lower rate than at present recommended, thereby enormously increasing the life and efficiency of the cells, and leaving a large surplus of energy in case of emergency. My own cells have been treated in this way, and I cannot see that they have in any way deteriorated after nearly five years' use. If the plates are kept free from sulphate, they may be bent to a considerable extent without suffering any damage, and if the grids are made of pure soft lead they may be readily straightened again. Certainly my experience leads me to recommend the use of soft lead grids in preference to those of a hard and brittle alloy. I consider that burning the lugs together is the most satisfactory way of connecting up the cells, but if brass screws and nuts are used they can be greatly protected by pressing some lead foil over and around them, this will keep off any acid spray which might reach them while the cells are being charged, and should any of the brass connections become corroded, I have found that they can be effectually cleaned without trouble by immersing them for a time in a solution of carbonate of soda, and then washing them thoroughly in pure water. If it is desired to use separators between the plates, a very simple and cheap way to make them is to use perforated porous paper which has been saturated in melted paraffin wax, this stands well in dilute acid, and I have some which have been in use for several years.

Although secondary batteries are now undoubtedly very efficient when carefully used for stationary purposes, it appears to me that as at present constructed they will not stand for any long period the wear and tear, shaking and washing of the liquid against the active material to which they must be subjected when used for traction purposes; at least such is the impression left on my mind after inspecting cells which have been used for even a short time; some of the plates generally soon show signs of buckling, and the bottoms of the cells became covered with disintegrated particles of the active material, which forms a sort of mud. I have endeavoured to overcome these defects by packing the plates in a solid though porous mass of plaster of Paris mixed with sawdust, and for three months a battery of 96 cells thus prepared was successfully running a tramcar at Canning Town and doing the same work as the other cars, however, at the end of this time the management passed into other hands, and I hear that the cells have been taken to pieces, as they were not giving satisfaction, so for the present this experiment has come to an end, and is apparently a failure, but I have not given up hopes that some modification of this plan may be successful, as for a time the working was very satisfactory. The proportion of plaster of Paris used in this experiment was two of plaster of Paris to one of sawdust, but I think the plaster of Paris was not pure, and its proportion was too great. I am now using a set of 22 Elwell-Parker cells, in which the proportion is  $2\frac{1}{2}$  of sawdust to 1 of plaster of Paris. The way I prepare the cells is to mix the plaster of Paris and sawdust intimately together in a dry state, and fill in the spaces between the plates with this mixture. I then pour in gently some dilute sulphuric acid to which a little carbonate of soda has been added, when the whole sets into a compact porous mass. After a time I pour in the electrolyte till it stands above the level of the tops of the plates, and it will be found that the cells will contain nearly as much liquid as if no porous material were used.

Last autumn I used a set of these cells in conjunction with a turbine and dynamo, and although they were last charged in November, I found on my return this year in June that they still retained the charge well after seven months' rest, and burnt the lamps brightly, the E.M.F. of each cell being just under 2 volts. Although in my experiments I have used plaster of Paris to insulate the particles of sawdust from each other, and to give stability to the porous mass, I have tried many other substances, both soluble and insoluble, mixed with it, but sawdust appears to act as well as anything which I have yet tried, and it has the advantage of being cheap, and easily procurable. This method of treating the cells would appear to be of no advantage in stationary work for electric lighting purposes, and would indeed be a distinct disadvantage, as owing to the want of free circulation of the liquid, the E.M.F. falls more rapidly under a long-continued heavy discharge, but it immediately recovers with a short interval of rest, and, in practice, these intervals are constantly occurring in electric traction, when the car stops to take up and set down passengers, and with cells treated in this way the vibration and shaking of the car is a positive advantage, as it facilitates the circulation of the electrolyte, and tends to liberate any occluded gases. The defect of this arrangement would appear to be that it must hinder the free circulation of the liquid and also add to the internal resistance of the cell, whilst, on the other hand, it prevents the plates from buckling, retains the active material firmly in its place, preserves the plates from injury, and

makes the cell very portable. I have ventured to mention this crude experiment in the hope that it may induce someone to produce a thoroughly practical cell for traction purposes which will stand rough usage and be free from the defects which at present exist.

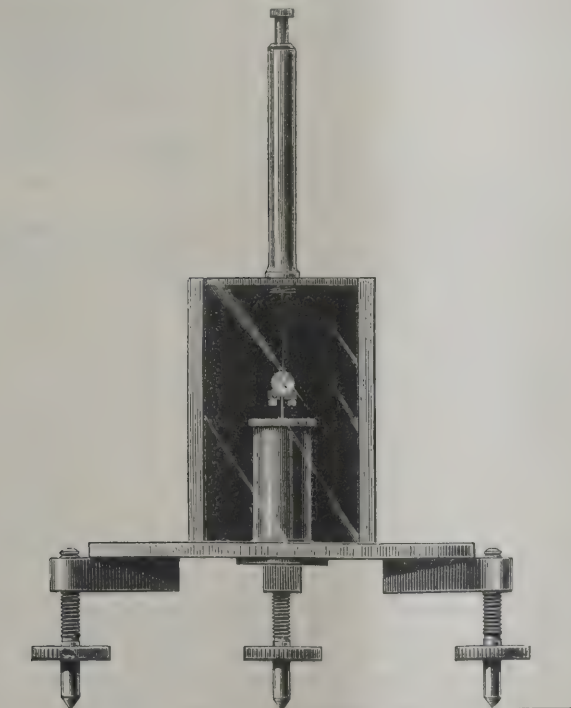

As regards the use of carbonate of soda in secondary cells, a case has just been brought to my notice which appears worthy of mention. I am told that at the Central News office, Ludgate Hill, 28 L. 13 cells had been lying dry and idle for upwards of two years, and each plate was encrusted with hard white sulphate: with ordinary dilute sulphuric acid and a charging current of 10 to 15 ampères, no difference was seen after two charges of eight hours per day; after adding about half a pint of strong carbonate of soda solution to the dilute sulphuric acid in the cells and doing the same electrical work as before, the plates were observed to change colour in a few hours, and in a few days each of the cells presented a beautiful appearance, not a single plate buckled, and I am told that the battery is working perfectly now. This entirely confirms my experience. After plates have been brought to a good condition by the use of carbonate of soda, the ordinary dilute sulphuric acid may be substituted for the mixed electrolyte if the cells are to be used for continuous work; but I believe a small amount of sodium salt is always beneficial; it, however, only becomes a necessity where cells have to stand idle for long periods.

ON THE CHARACTER OF STEEL USED FOR  
PERMANENT MAGNETS.

By W. H. PREECE, F.R.S.

(Read before Section A, September 9th, 1890.)

In the discussion which followed the reading of Dr. John Hopkinson's Presidential address to the Institution of Electrical Engineers, I took the opportunity to point out that the quality of magnetic steel in England had deteriorated, and that it was not to be compared with that produced in France in 1881. This statement was questioned at the time, and I determined to make an exhaustive test of the various steels that are now in the market. Specimens were therefore obtained from the leading firms in Sheffield, viz., Messrs. Joseph Ashforth and Company, Messrs. Saunderson Bros. & Co., Messrs. Thos. Jowitt and Sons, Messrs. Vickers, Sons & Co., and Mr. G. P. Wall, and also from the following manufacturers in France: M. Marchal and M. Clemandot. Mr. Webb, of Crewe, also gave me some samples of the steel used in those works.

MAGNETOMETER.

The magnetometric method has been followed throughout this enquiry. Square bars, approximately 10 cm. long and 1 sq. cm. in section, were chosen as test pieces in preference to the long wires, ellipsoids, or other special forms of magnet usually employed in very accurate investigations. These bars are comparable in dimensions with the magnets actually employed for telegraphic purposes; they are very convenient for use with the magnetometer, they can be kept in a relatively small compass for periodical testing, and they enable us to compare the magnetic qualities of different steels with very great accuracy. Although they can only be regarded as approximately solenoidal, and are much too short for theoretical exactness, yet it is believed that the values of the induction, intensity of mag-

netisation, and specific magnetism, calculated from the magnetic moments of the various specimens, are sufficiently accurate to be of scientific interest. In order to facilitate calculation, it was desirable that the bars should be exactly 10 cm. long, by 1 sq. cm. in section, but it was found that the specimens received could not be worked to this size. I have therefore determined their dimensions and weights by careful measurements, and have given the details in the subjoined tables.

All the English specimens were carefully and uniformly tempered in water in accordance with our usual practice. Of the four magnets made of Allevard steel two were tempered in water, and two in mercury. The Clemandot compressed steel and the Marchal magnets were already tempered and magnetised when received from Paris.

For magnetising the bars a powerful electromagnet (of a form suggested by Prof. Perry) was employed (fig. 1).

The coil of the electro-magnet is wound with 136 turns of .508 c.m. copper wire, the length of the coil between the cheeks being 9.3 cm. The soft iron core is 10 cm. long and 3 cm. in diameter, and the pole-pieces are 11.5 cm. long and 3 cm. square. The upper pole-piece (which may be removed and replaced by one of a form suitable for maximum induction experiments) is furnished with a thumb-screw and a small movable block, so that the bars to be magnetised may be clamped in position, care being taken that their ends make perfect contact with the pole-pieces.

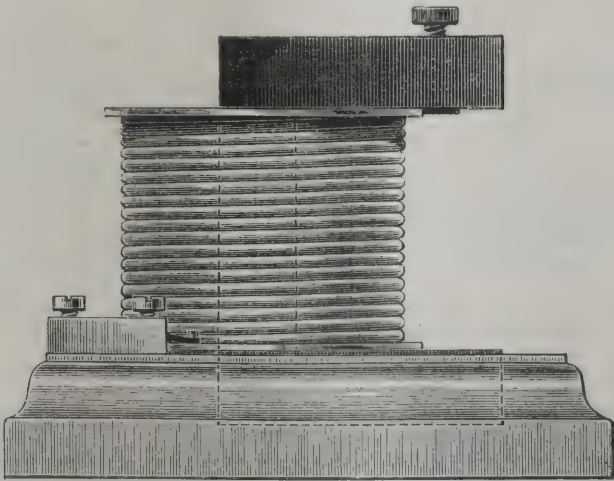

In the first series of experiments the magnetising current employed was 100 ampères (13,600 ampère-turns), and it was kept on for 30 seconds for each bar.

In the second series the current was increased to 325 ampères (41,200 ampère-turns), and kept on for three seconds in each case. Generally speaking this increased current did not increase the permanent magnetisation of the bars; but, on the contrary, the magnetisation was, in most cases, apparently slightly less than it was after magnetisation with 100 ampères three months previously. The magnetisation of the Clemandot and Marchal magnets was, however, considerably increased by the same treatment, as will be seen from the tabulated result of the experiments.

The magnetometer employed is simply a Thomson mirror, suitably mounted with levelling screws, and placed over the centre of a millimetre scale two metres long. The scale for reading the deflections is of the usual straight kind with central zero, and is placed at a constant distance of 100 cm. from the mirror. The magnets were, in most cases, tested with their centres at distances of 100 and 75 cms. from the mirror, and the mean of readings on either side of zero in each position was taken. The moments have been

calculated from the formula:  $M = \frac{H}{2} \frac{(r^2 - l^2)^2}{r} \tan. \theta$ ;  $r$  being the distance of the magnet from the mirror, and  $l$  half the length of magnet (= 5 cms. very nearly).

The maximum value of  $2 \theta$  being only about  $4^\circ$ ,  $\tan. \theta$  has been taken as equal to  $\frac{\tan. 2 \theta}{2}$ .

MAGNETISING ELECTROMAGNET.

The value of  $H$  for the room in the General Post Office in which the first series of experiments were made was determined both by the coil method and by the method of vibrations.

1. Experiments with a coil of 18 turns, and a mean radius of (15.6) cms.:—

2. Experiments with glass hard magnetised wires.—H calculated from the formula,  $H^2 = \frac{8 \pi r k}{T^2 (r^2 - l^2)^2 \tan \theta}$ .

June 15th.	Moment of inertia K.	r.	Deflect.	Tan. θ	Time of complete vibration, T.	H.	Mean.
No. 1 wire..	5·6421	Min. 400	Mm. 17·58	·00879	Secs. 7·075	·1278	1·277
2 „ ..	5·574	„	12·14	·006069	8·462	·1278	
3 „ ..	5·574	„	17·48	·008738	7·062	·1276	

The values of H thus obtained, although agreeing closely with each other, being surprisingly low, the same wire magnets were taken to a spot 4 or 5 miles from the G.P.O., and it was then found that their periods of vibration were reduced respectively to 5·99, 7·14, and 5·95 seconds, making H about ·1782, and showing that the previous determinations were fairly accurate.  
During the second series of experiments the following values of H were obtained by the coil method:—

Date.	Current ampere.	Distance of coil from mirror.	Mean Deflection.	Tan. θ	H.	Mean value of H.

If we take the mean induction of the magnets of each group, which is probably a fairer method of comparison, we obtain a slightly different order, viz.:

	Mean Induction.

The marked superiority of the Marchal magnets over those made of English steel is evidently not due to the method of magnetisation adopted by the maker, since their mean induction was increased by 38 per cent., and their magnetisation rendered more uniform by re-magnetisation in our coil. Their greater strength must therefore be due either to the quality of the steel, or to the

mode of tempering—most probably the latter. The Clemandot compressed steel magnets, too, which were very poor when first tested, had their mean induction more than doubled by re-magnetisation.

In view of the results of these experiments, I purpose to investigate further the methods of tempering magnet steel. It is pretty clear there is room for improvement in our present practice.

I am indebted to M. Trotin, of the French Telegraphic Administration, for having kindly procured the French specimens for me.

The induction in these short straight bars is comparatively low, because we measure only the lines (Maxwell's B) that radiate from the ends. Prof. Perry has succeeded in getting as much as 12,700, with Jowitt steel, through the middle of a magnet of a special horseshoe form. It ought, apparently, to be possible to get about 20,000 with the best French steel.

I happen to have in my possession two small horseshoe magnets of Allevard steel which were made for Mr. H. Edmunds, and magnetised in Paris in 1881. The induction of one is now 3,287·3, and of the other 3,552·5. They have never been touched since 1881. The retentiveness is therefore very good.

All these measurements have been made with great patience and skill by Mr. Henry Hartnell.

## ON ANTI-EFFECTIVE COPPER IN PARALLEL CONDUCTORS OR IN COILED CONDUCTORS FOR ALTERNATE CURRENTS.

By Sir WM. THOMSON.

(Read Before Section A, September 5th, 1890.)

1. It is known that by making the conductors of a circuit too thick, we do not get the advantage of the whole conductivity of the metal—copper, let us say—for alternate currents. When the conductor is too thick, we have in part of it comparatively ineffective copper present; but, so far as I know, it has generally been supposed that, the thicker the conductor, the greater will be its whole effective conductance, and that thickening it too much can never do worse than add comparatively ineffective copper to that which is most effective in conveying the current. It might, however, be expected that we could get a positive augmentation of the effective ohmic resistance, because we know that the presence of copper in the neighbourhood of a circuit carrying alternate currents, causes a virtual increase of the apparent ohmic resistance of the circuit, in virtue of the heat generated by the currents induced in it. May it not be that, anti-effective influence, such as is thus produced by copper not forming part of the circuit, can be produced by copper actually in the circuit if the conductor be too thick? Examining the question mathematically, I find that it must be answered in the affirmative, and that great augmentation of the effective ohmic resistance is actually produced if the conductor be too thick; especially in coils consisting of several layers of wire laid over one another in series around a cylindric or flat core (as in various forms of transformers).

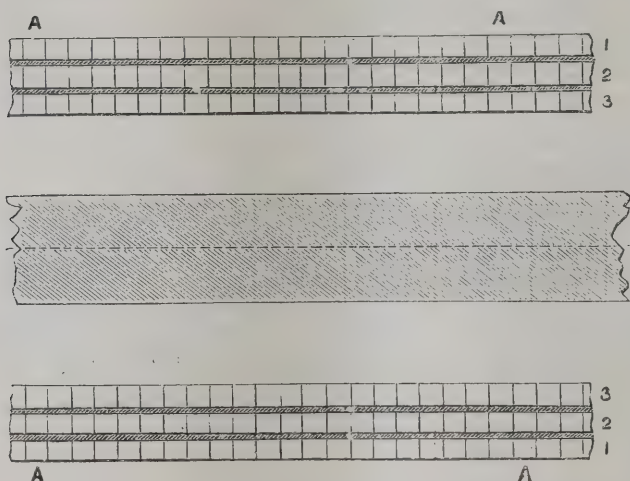

FIG. 1.

2. Fig. 1 may be imagined to represent the secondary coil of a transformer consisting of solid square copper wire in three layers. For simplicity, we suppose the axial length to be infinitely great, and straight; but the uniformity which this involves, and a close practical application to its simplicity is realised in that excellent form of transformer which consists of a toroidal iron core completely covered by primary and secondary wires laid on toroidal surfaces. To simplify the mathematical work, I suppose the whole thickness of the three layers to be small in comparison with the greatest radius of curvature of the circular or flat cylindric surface on which the wire is wound, but if it is not so the solution is easily obtained, for the case of circular cylinders, in terms of the Fourier-Bessel functions. It is of no consequence for our present question what there be inside of coil No. 3, and if we please we may imagine there to be nothing but air; the drawing, however, indicates an iron core and space which might be occupied by the primary coil, if a transformer is the subject; or our coil, A, A, A, A, may be the primary coil of a transformer with secondary coil and core inside it, and the alternate current maintained in it by an external electromotive agent acting in an arc between its ends outside. Our present results are applicable to all these varieties of cases indifferently, all that is essential being that the total quantity of current be given at each instant, and be uniform throughout the whole length of the coiled conductor.

3. This last condition is secured by perfectness of insulation between all contiguous turns of the coil, unless we were considering so enormously long a coil that the quantity of electricity required for the essential changes of static electrification would be sensible as constituting drafts from, or contributions to, the current in the coil. The consideration of static electrification involved in the maintenance of alternate currents through a coil such as that represented in fig. 1, is exceedingly curious and interesting; but we do not enter on it at present at all, as in all practical cases the quantities concerned are quite infinitesimal in comparison with the whole quantity flowing in one direction or the other in the half period.

4. In the drawing, the section of the wires is represented as square, but this is not essential, and in practice a flat rectangular

ribbon would, no doubt, for some dimensions of coils, be preferable. I assume the thickness of the insulation between the successive squares or rectangles in each layer to be infinitely small in comparison with the breadth of the rectangle; but the thickness of the insulation between successive layers, which is a matter of indifference to my calculations, may be anything, and would in practice naturally be, as shown in the diagram, considerably greater than the thickness of the insulation between the contiguous portions of the coil in each layer.

5. The full mathematical work which I hope to communicate to the *Philosophical Magazine* for publication in an early number, includes an investigation of the self-induction of the coil, with or without anything in its interior (such as core, or primary wire of a transformer), but, at present, I merely give results so far as effective ohmic resistance, or generation of heat in the interior of the wire of the coil, A, A, A, A, itself is concerned; which, as said above, is independent of everything in the interior, and of the mode in which the alternating current is produced, provided only that the total amount of electricity crossing the section of the wire per unit of time be given at each instant.

6. As a preliminary to facilitate the expression of these results, it is convenient first to give a general statement of the solution of the problem of laminar diffusion of a simple harmonic variation, applied to the case of electric currents in a homogeneous conductor. Let the periodically varying magnetic force in the air or other insulating material in the neighbourhood of so small a portion,  $s$ , of the surface of a conductor that we may regard it as plane be given. Resolve this magnetic force into two components, one perpendicular to  $s$  which we may neglect, as it has no influence in connection with the currents we are to consider; the other parallel to  $s$ , which we shall call the effective component, and denote by  $\gamma$ . Through any point,  $o$ , of  $s$ , draw three rectangular lines,  $ox$ ,  $oy$ ,  $oz$ , of which  $oy$  and  $oz$  are in  $s$ , and  $ox$  is parallel to the direction of the directive magnetic force component,  $\gamma$ . Let now the value of  $\gamma$  at time,  $t$ , be

$$\gamma = M \cos \frac{2\pi t}{T},$$

where  $M$  denotes a constant, and  $T$  the period of the alternation. The varying magnetic force,  $z$ , to whatever cause it may be due, gives rise to currents parallel of  $oz$  in the conductor, expressed by the following formula for  $\gamma$ , the current intensity at distance,  $x$ , from the plane,  $s$ , provided  $x$  be small enough to fulfil the condition stated below:—

$$\gamma = \frac{M}{\lambda \sqrt{2}} e^{-\frac{2\pi x}{\lambda}} \cos \left( \frac{2\pi t}{T} - \frac{2\pi x}{\lambda} + \frac{1}{2}\pi \right),$$

where  $\lambda$  denotes what we may call the wave length of the disturbance and is given in the terms of  $T$ , the period of the disturbance, and  $\rho$  and  $\omega$  the resistivity and magnetic permeability of the substance, by the following formula:—

$$\lambda = \sqrt{\frac{T\rho}{\omega}}.$$

For copper we have  $\omega = 1$ , and  $\rho = 1611$  square centimetres per second; and thus for 80 periods per second  $\lambda = 4.49$  or, say,  $4\frac{1}{2}$  centimetres.

In order that the formula for  $\gamma$  may be approximately true, it is necessary, in the first place, that  $\lambda$  must be small in comparison with the distance we must travel in any direction in the surface of  $s$ , before finding any deviation of it from the tangent plane through  $o$ , comparable with  $\lambda$ . Secondly, for a very good approximation,  $\lambda$  must be so small that we may be able to travel inwards, in any direction from  $o$ , through a space equal to at least twice  $\lambda$ , without coming to any other part of the bounding surface of the conductor. If, for example, the surface be a flat plate, this condition requires that the thickness be more than twice  $\lambda$ . But (because  $e^{-\pi}$  is less than  $1/23$ ), the formula gives a very fair approximation, requiring for a half the thickness of the plate inwards from  $s$  no greater correction than about 4 per cent, even if the thickness of our plate be no greater than  $\lambda$ . When the thickness of the plate is less than  $2\lambda$ , we may consider waves of electric current as travelling inwards from its two sides and being both sensible at the middle of the plate; and a complete solution of the problem is readily found by the method of images. But, a direct analytical investigation, by which the proper conditions of relation to varying magnetic force on the two sides of the plate are fulfilled is the most convenient way of fully solving the problem, and it is thus that the results given below have been obtained.

7. The smallness of the insulating space between the successive turns in each layer of our coil A, A, A, A, and the equality of the whole current through them all, prevent any surface disturbance from being produced at the contiguous faces, and allow the problem to be treated as if, instead of a row of squares or rectangles we had a continuous plate forming each stratum. The smallness of the thickness of this plate in comparison with the radius of the cylindric surface to which it is bent, allows, as said above, the mathematical treatment for an infinite plate bounded by two parallel planes to be used without practical error. I have thus found an expression for the intensity of the current at any point in the metal of any one of the layers of a coil of one, two, three, or more layers; and have deduced from it an expression for the quantity of heat generated per unit of time, at any instant, per unit breadth in any one of the layers. I need not at present quote the former expression; the latter is as follows. With  $q$  to denote

the dynamical value in time average of the heat generated, per unit of time at different instants of the period, per unit breadth and unit length in layer No.  $i$  from the outside of the coil,  $c^2$  the time average of the square of the total current per unit breadth, and  $a$  the thickness of the layer

$$q = \frac{2 \pi \rho}{\lambda} \rho \Theta c^2$$

where  $\Theta = \frac{\epsilon^2 \theta + 2 \sin 2 \theta - \epsilon^{-2 \theta}}{\epsilon^2 \theta - 2 \cos 2 \theta + \epsilon^{-2 \theta}} + 2 i(i-1) \frac{\epsilon^{\theta} - 2 \sin \theta - \epsilon^{-\theta}}{\epsilon^{\theta} + 2 \cos \theta + \epsilon^{-\theta}}$

and  $\theta = \frac{2 \pi a}{\lambda}$ .

8. The numerical results shown in the table have been calculated, and the accompanying graphic representation (fig. 2), drawn, for me by Mr. Magnus Maclean.

TABLE OF VALUES OF  $\theta$ .

$\frac{16 \theta}{\pi}$	$i = 1$	$i = 2$	$i = 3$	$i = 4$
1	5.113	5.118	5.127	5.141

$\infty$	—	5.00	13.00	25.00

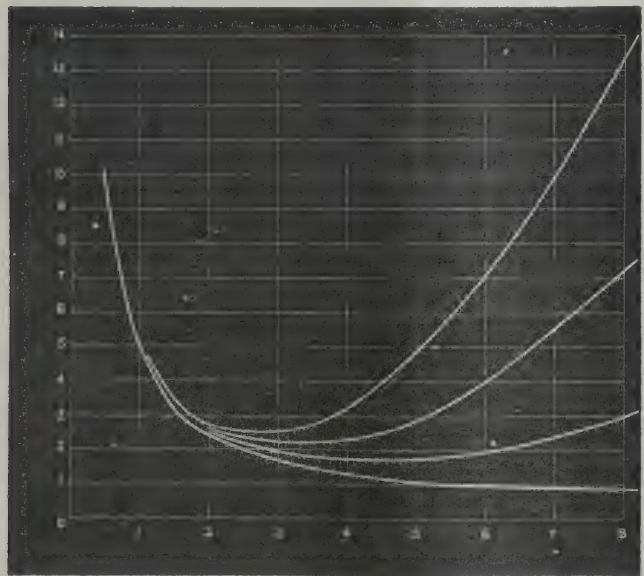

FIG. 2.

8. We see from the table and curves that each curve has a minimum distance from the line of abscissas, and that each comes to a horizontal asymptote, parallel to the line of abscissas, for  $\theta = \infty$ . By looking at the formula, we see that there is, in fact, an infinite succession of minimums and maximums in the expression for  $\Theta$ , but it is only the first minimum, and the following maximum, that occur within the range of variation of  $\theta$ , which we regard as sensible. In the case of  $i = 1$ , the formula gives  $\theta = \frac{1}{2} \pi$  for the first minimum. The curves show for the case of  $i = 2, 3, 4$ , respectively, the first minimum at  $\frac{16 \theta}{\pi} = 4\frac{1}{2}, 3$ , and  $2\frac{6}{10}$ , respectively. The thickness which corresponds to  $\theta = \pi$  is the half wave length of the electric disturbance, which, as we have seen is for copper 2.244 centimetres, when the frequency of the alternations is 80 periods per second; and for this case, therefore, the thicknesses that give minimum generation of heat in the first, second, third, and fourth layers are, respectively, 11.22, 6.31, 4.21, and 3.65 millimetres. Anything more of continuous copper than these thicknesses in any of the layers would be not merely ineffective or comparatively ineffective, but would be positively anti-effective. Even with so small a thickness as 2.8 millimetres, for copper and frequency 80, line 2 of the table (corresponding to a sixteenth of the wave-length) shows, in the first, second, third, and fourth layers, losses of 0.3 per cent., 2 per cent., 5 per cent., and 10 per cent. in excess of that due to the true ohmic resistance of the copper, were it all effective. When the size chosen for the transformer and the amount of output required of it are such that a thickness of  $2\frac{1}{2}$  millimetres in the direction perpendicular to the

layers is insufficient, a remedy is to be had by using braided wire, or twisted strand, with slight insulation of varnish or whitewash, crushed or rolled into rectangular or square form of the desired thickness and breadth. A very slight resistance between the different wires thus crushed together would suffice to cause the current to run nearly enough full bore to do away with any sensible loss from the cause which forms the subject of this communication.

ON THE FORM OF SUBMARINE CABLES FOR LONG  
DISTANCE TELEPHONY.

By W. H. PREECE, F.R.S.

(Read before Section G, September 9th, 1890.)

At the Newcastle meeting last year, I gave the reasons and experiments which led to the conclusion that telephoning between London and Paris was practical. New and distinct aerial lines of four copper wires are now being erected by the respective governments from each capital to the coast, and a new cable, the joint property of the two governments, will be laid during this year, between the Kent coast and Sangatte, to connect these two lines. There will thus be two metallic circuits between the two capitals. The  $\kappa \epsilon$ , that is the product of the capacity,  $\kappa$ , and the resistance,  $\epsilon$ , of each circuit, upon which the clearness of articulation depends, will be 5,900, indicating that speech should be excellent.

A somewhat similar circuit has been established, since October last, between Buenos Ayres and Monte Video, under my advice. The cables across the La Plata are each 28 miles long, for there are two separate single wire cables, and the total distance between the two cities is 180 miles. Subscribers, who have metallic circuits in each city, have no difficulty whatever in speaking to each other from their respective offices, although the  $\kappa \epsilon$  is as high as 10,400.

The cable across the Channel will be a four-wire cable, and the specification for its construction has been based on the following mathematical development by Mr. H. E. Kempe.

Let there be a looped telephonic line between A and B, with a cable c, at an intermediate point on the route.

The working capacity of the whole line is dependent upon the product of the total resistance,  $\epsilon$ , and the total capacity  $\kappa$ . Therefore, if we take the resistance of the aerial portion of the line to be a fixed quantity, there will be a particular size of cable conductor which will give the smallest possible size of dielectric, sufficient to enable a particular value of  $\kappa \epsilon$  not to be exceeded. For, if we make the conductor larger than this size, and thereby diminish its resistance, we can, it is true, do with an increased capacity, but the diminution in the thickness of the dielectric which could thereby be allowed, is more than compensated for by the fact that the surface of the conductor is larger; in other words, we increase the capacity in a greater proportion than we diminish the resistance. If, on the other hand, we diminish the size of the conductor, we increase the resistance in a greater proportion than we diminish the capacity. Strictly speaking, the requirements of the problem are to determine the size of cable core which shall cost least; but inasmuch as the costs of gutta-percha and copper, bulk for bulk, do not differ greatly, the problem resolves itself into the determination of the smallest outer diameter which can be employed.

Let

$r$  = total resistance of aerial line,  
 $\rho$  = " " " cable,  
 $k$  = " capacity of aerial line,  
 $\kappa$  = " " " cable.

Then

$\kappa \epsilon = (k + \kappa) (r + \rho).$

Let

$D$  = diameter of dielectric of cable,  
 $x$  = " " conductor " "

Then

$\rho = \frac{a}{x^2}$  and  $\kappa = \frac{b}{\log_{\epsilon} \frac{D}{x}}$

where  $a$  and  $b$  are constants.

We have, therefore,

$\kappa \epsilon = \left( k + \frac{b}{\log_{\epsilon} \frac{D}{x}} \right) \left( r + \frac{a}{x^2} \right)$

therefore

$\log_{\epsilon} \frac{D}{x} = \frac{\kappa \epsilon}{r + \frac{a}{x^2}} - k = \frac{\kappa \epsilon - k \left( r + \frac{a}{x^2} \right)}{r + \frac{a}{x^2}}$

therefore

$\log_{\epsilon} \frac{D}{x} = \frac{b \left( r + \frac{a}{x^2} \right)}{\kappa \epsilon - k \left( r + \frac{a}{x^2} \right)}$

therefore

$$\log_{\epsilon} D = \frac{b \left( r + \frac{a}{x^2} \right)}{KR - k \left( r + \frac{a}{x^2} \right)} + \log_{\epsilon} x$$

$$= \frac{r + \frac{a}{x^2}}{\frac{KR - k r}{b} - \frac{k a}{b x^2}} + \log_{\epsilon} x = \frac{\frac{r}{a} + \frac{1}{x^2}}{\frac{KR - k r}{a b} - \frac{k}{b x^2}} + \log_{\epsilon} x$$

$$= \frac{A + \frac{1}{x^2}}{B - \frac{C}{x^2}} + \log_{\epsilon} x = u, \text{ say}$$

where

$$A = \frac{r}{a}$$

$$B = \frac{KR - k r}{a b}$$

$$C = \frac{k}{b}$$

Now to make  $D$  a minimum we must make  $\log_{\epsilon} D$  (that is  $u$ ) a minimum, and this we have to do by variation of  $x$ , therefore we have

$$\frac{d u}{d x} = \frac{1}{\left( B - \frac{C}{x^2} \right)^2} \left\{ \left( B - \frac{C}{x^2} \right) \frac{2}{x^3} - \left( A + \frac{1}{x^2} \right) \frac{2 C}{x^3} \right\} + \frac{1}{x} = 0$$

therefore

$$\frac{1}{x} = \frac{1}{\left( B - \frac{C}{x^2} \right)^2} \left\{ \left( B - \frac{C}{x^2} \right) \frac{2}{x^3} + \left( A + \frac{1}{x^2} \right) \frac{2 C}{x^3} \right\}$$

$$= \frac{2}{x^3 \left( B - \frac{C}{x^2} \right)^2} \left\{ \left( B - \frac{C}{x^2} \right) + \left( A + \frac{1}{x^2} \right) C \right\}$$

$$= \frac{2}{x^3 \left( B - \frac{C}{x^2} \right)^2} \{ B + A C \}$$

therefore

$$x^2 \left( B - \frac{C}{x^2} \right)^2 = 2 \{ B + A C \}$$

therefore

$$x \left( B - \frac{C}{x^2} \right) = \sqrt{2 \{ B + A C \}}$$

therefore

$$B x - \frac{C}{x} = \sqrt{2 \{ B + A C \}}$$

therefore

$$x^2 - \frac{x \sqrt{2 \{ B + A C \}}}{B} = \frac{C}{B}$$

From which, by solving the quadratic equation, we get

$$x = \frac{\sqrt{B + A C} + \sqrt{B + A C + 2 B C}}{\sqrt{2 B}}$$

Now, careful experiments made on an aerial line of copper wire, weighing 200 lbs. per mile (diameter = 112 mils.), the wire being 30 feet above the ground showed that the inductive capacity per mile was .015 microfarads very nearly, consequently the capacity per mile is expressed by the formula

$$\frac{.061637}{6.1583625 - \log d}$$

$d$  being the diameter of the wire in mils.

From this formula the capacity per mile of a wire weighing 400 lbs. works out .0156 m.f. The average resistance per mile of a wire of this weight is 2.25 ohms.

Taking the distance between London and Dover to be 70 miles, and between Calais and Paris to be 180 miles, the total distance of the loop will be 500 miles, which for a 400 lbs. copper wire gives the resistance

$$r = 500 \times 2.25 = 1,125 \text{ ohms.}$$

Now, in the case of a looped wire, the total capacity equals half that of a single wire, hence

$$k = \frac{.0156 \times 250}{2} = 1.95.$$

Assuming the length of the cable to be 21 knots, we have approximately

$$\rho = \frac{42 \times 74,402}{x^2} \text{ for copper of 98 per cent. conductivity at } 60^\circ \text{ F.}$$

so that

$$a = 3,124,884.$$

The ordinary standard core used by the Post Office has a con-

ductor diameter of 86.41 mils., and a gutta-percha diameter of 285 mils., and a capacity of 1/3 m.f. per knot, and as

$$\text{capacity per knot} = \frac{\text{const.}}{\log \frac{D}{d}}$$

we have

$$1/3 = \frac{\text{const.}}{\log \frac{285}{82.087}}$$

or

$$\text{const.} = \frac{\log \frac{285}{82.087}}{3} = .18018997$$

The capacity of 42 knots of looped cable will be half that of 21 knots of single cable, hence

$$K = \frac{.18018997 \times \frac{21}{2}}{\log \frac{D}{a}} = \frac{1.8919947}{\log \frac{D}{a}}$$

$$= \frac{4.356481}{\log_{\epsilon} \frac{D}{x}}$$

so that

$$b = 4.356481$$

We have then for 400 lbs. wire

$$a = 3,124,884$$

$$b = 4.356481$$

$$r = 1,125$$

$$k = 1.95$$

If we take  $KR = 7,500$ , which is the highest value that can safely be taken, we get

$$B = \frac{7,500 - 1.95 \times 1,125}{3,124,884 \times 4.356481} = .000389779$$

$$2 B C = \frac{2 \times .000389779 \times 1.95}{4.356481} = .000348937$$

$$\sqrt{2 B} = .000551231$$

$$A C = \frac{1.95 \times 1,125}{3,124,884 \times 4.356481} = .0001611454$$

From this we get

$$\sqrt{B + A C} = .02347177$$

$$\sqrt{B + A C + 2 B C} = .0299977$$

$$\sqrt{2 B} = .000551231$$

$$\text{so that } x = \frac{.02347177 + .0299977}{.000551231} = 97.00014$$

$$\text{and extreme diameter of strand} = 97.00014 \times \frac{100}{95} = 102.1054 \text{ mils.}$$

Since  $KR = (k + \kappa) (r + \rho)$

we get

$$\kappa = \frac{KR}{r + \rho} - k$$

$$= \frac{7,500}{1,125 + \frac{3,124,884}{(97.00014)^2}} - 1.95 = 3.197153$$

But

$$\kappa = \frac{1.89199468}{\log \frac{D}{x}}$$

therefore

$$\log D = \frac{1.89199468}{\kappa} + \log x = \frac{1.89199468}{3.197153} + 1.9867724$$

$$= 2.5785475 = \log \text{ of } 378.86$$

$$= 380 \text{ mils approximately.}$$

If we take

$$x = 95 \quad \text{then } D = 378.94$$

$$,, \quad 97.00014 \quad ,, \quad 378.86$$

$$,, \quad 99 \quad ,, \quad 379.08$$

which proves the correctness of the calculation for a minimum.

The values of these diameters correspond very closely to a core, the weight of whose conductor is 160 lbs., and the weight of whose gutta-percha covering is 300 lbs., and it has therefore been decided to adopt those dimensions.

Although the calculation has been made on the assumption that the land lines on both sides of the cable are to be of 400 lbs. wire, the French Government have decided that the wires to be erected by them shall be of 600 lbs. weight; the result of this will be to reduce the value of  $KR$  to 5,900, as stated at the commencement of the paper.

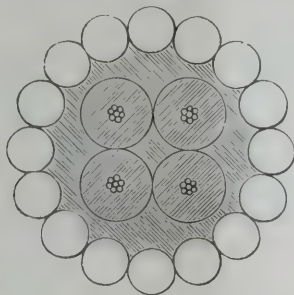

The specification of the cable states that:—(1) Each conductor shall be formed of a strand of seven copper wires all of equal diameter, shall weigh 160 lbs. per nautical mile, and shall at a temperature of  $75^\circ$  Fahrenheit have a resistance not higher than 7.632 ohms or lower than 7.478 ohms per nautical mile.

(2) Each conductor shall be insulated by being covered with

three alternate layers of Chatterton's compound and gutta-percha, beginning with a layer of the said compound, and no more compound shall be used than may be necessary to secure adhesion between the conductor and the layers of gutta-percha. The dielectric on each conductor shall weigh 300 lbs. per nautical mile, making the total weight of each conductor when covered with the dielectric 460 lbs. per nautical mile.

(3) The inductive capacity of such insulated conductor shall not exceed '3045 microfarad per nautical mile.

(4) The insulation resistance of each coil of core shall be not less than 500 megohms per nautical mile after such coil shall have been kept in water maintained at a temperature of 75° Fahrenheit for not less than 24 consecutive hours immediately preceding the test, and after electrification during one minute.

The cores (four in number) are to be served with the best wet fully tanned yarn, and with a sheathing of 16—280 mil. wires, each having a minimum breaking strain of 3,500 lbs., and a minimum of 10 twists in 6 inches. The section of the cable is shown by the fig.

#### SUGGESTIONS TOWARDS A DETERMINATION OF THE OHM.

By Prof. J. V. JONES, Principal and Professor of Physics in the University College of South Wales and Monmouthshire, Cardiff.

(Read in conjunction with the Discussion on Electrical Units, in Section A, September 5th, 1890.)

"ON the whole I am of opinion that if it is desirable at the present time to construct apparatus on the most favourable scale so as to reach the highest attainable accuracy, the modification of Lorenz's method, last described, is the one that offers the best prospect of success. Before this is done, however, it appears to me important that the value now three times obtained in the Cavendish Laboratory, by distinct methods, should be approximately verified (or disproved) by other physicists. To distinguish between this value and those obtained for instance by Kohlrausch, by Lorenz, or by the first B. A. Committee, should not require the construction of unusually costly apparatus. Until the larger question is disposed of, it seems premature to discuss the details of arrangements from which the highest degree of precision is to be expected."

The above passage which concludes a paper communicated by Lord Rayleigh to the *Philosophical Magazine*, in November, 1882, nearly two years before the Electrical Congress at Paris, at which the legal ohm was defined to be the resistance of a column of mercury of 1 sq. mm. section and 1,060 mm. long, seems not to have met with adequate response in this country. So far as published experiments in English laboratories are concerned, the determination of the ohm remains where Lord Rayleigh left it, except for the contribution made by Glazebrook and Fitzpatrick in their measurement of the specific resistance of mercury in terms of the B.A. unit, which is one of the elements in the determination of the specific resistance of mercury in absolute measure by Lord Rayleigh's adaptation of Lorenz's method.

But though in England the scientific world has during the last seven or eight years occupied itself with other things, in other countries, and more especially in America and France, measurements have been made which have confirmed the Cavendish Laboratory result as against the other values mentioned by Lord Rayleigh in the passage quoted. Further, indication has already been given of the intention to employ as the unit of electrical resistance in the new Government Standardising Laboratory not the so-called legal ohm but the true ohm as nearly as it can be determined, and Major Cardew in the paper recently read by him before the Institution of Electrical Engineers has invoked the assistance of Lord Rayleigh and the British Association Electrical Standards Committee in the preparation of the required unit. The work judged necessary by Lord Rayleigh before the conditions of a more accurate determination could be advantageously discussed having been done; and practical necessity for an authoritative determination having arisen in connection with the standardising laboratory, the time seems ripe for a consideration of arrangements likely to secure high accuracy, and it is with this view that I venture to bring before the section the suggestions embodied in this paper.

In the hope of paving the way for a more accurate determination (and initially moved to the work by the invitation given in the passage which I first read) I have for a considerable time been engaged in submitting to the test of experiment certain modifications of the method of Lorenz which occurred to me as likely to lead to increased accuracy and certainty. I do not propose to

trouble the section with the details of these experiments, which I hope may be published elsewhere. I mention them merely to give the suggestions brought forward the support derived from a determination actually made on the lines indicated. The experiments have been made in the laboratory of the University College at Cardiff with apparatus for the most part constructed in the college workshop. Five complete sets of observations were taken in the spring of this year with the following results for the specific resistance of mercury at 0° C. :—

(i.)	94,103	absolute units
(ii.)	94,074	" "
(iii.)	94,093	" "
(iv.)	94,045	" "
(v.)	94,021	" "

Mean 94,067 ± 10 (probable error). The result may be otherwise expressed by saying that the ohm is equal to the resistance of a column of mercury of 1 square mm. sectional area, and 106·307 centimetres long, the probable error being ± 0·012.

It is far from my intention to bring these numbers forward as the best determination possible by the method I have used. I do not think they at all represent the accuracy attainable if the apparatus were to be constructed on a scale a little larger, and with a certain perfecting of detail. Undersuch circumstances I am of opinion that a single set of observations will give a result accurate to one part in ten thousand, and that as a mean of a number of observations we may, perhaps, aim at the hundred-thousandth if regard is paid to the maintenance of definite temperatures in all parts of the apparatus, and if we can be said to know our length standards to this degree of accuracy.

In Lorenz's method a metallic disc is made to rotate in the mean plane of a coaxial standard coil. Wires touching the centre and circumference of the disc are led to the ends of the resistance to be measured, and the same current is passed through this resistance and the standard coil. The connections being rightly made we may, by varying either the rate of rotation of the disc or the resistance to be measured, so arrange matters as to have no change of current in the circuit of the disc and wires joining it to the ends of the resistance when the direction of the current through the resistance and the standard coil is changed. When this arrangement is effected there is a balance between the electromotive force due to the motion of the disc in the magnetic field of the current in the standard coil, and the difference of potential at the ends of the resistance due to the current traversing it. If this adjustment is made, let us say that the apparatus is in an equilibrium position.

If  $M$  = the coefficient of mutual induction of the standard coil and the circumference of the disc;

$n$  = the rate of rotation of the disc (number of revolutions per second);

$R$  = the resistance;

$\gamma$  = the current through the standard coil and resistance;

then, in an equilibrium position,

$$M n \gamma = R \gamma$$

or

$$M n = R.$$

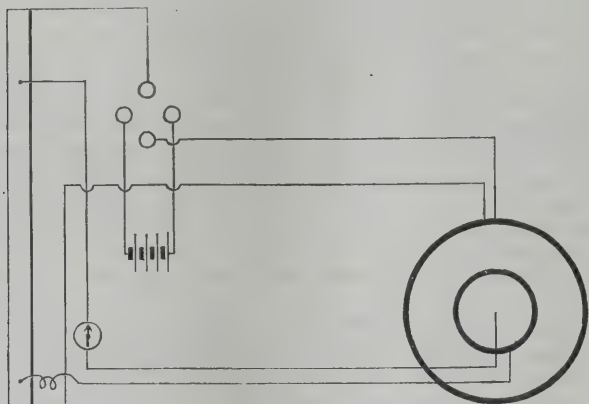

In practice it is not possible to take the coefficient of mutual induction and the rate of rotation large enough to make the measured resistance more than a small fraction of an ohm\*; and this has usually been regarded as one of the difficulties of Lorenz's method.

In order that the absolute unit may be recoverable at pleasure without the fatigues of a new absolute determination, it must be defined in practice by reference to the specific resistance of some standard substance, and for many reasons there is a consensus of opinion in making this standard substance mercury. The determination of the ohm as a practical problem, therefore, becomes identical with the determination of the specific resistance of mercury in absolute measure, and the small resistance measured by the method of Lorenz's must, in order to complete the investigation, be brought into relation and compared with the specific resistance of mercury. Lorenz himself evaded the difficulty by taking for his measured resistance the resistance of a mercury column contained in a glass tube; the resistance of the column was then obtained in absolute measure, and the specific resistance calculated from the dimensions of the column. It is hardly possible, however, that the latter calculation can have been, or is likely to be, achieved with accuracy, however accurately the tube be calibrated. For, on the one hand, if the wires from the disc (the terminal portions of which may be called the electrodes) are led to the ends of the tube, the equipotential surfaces touched by them are not plane; and, on the other, if they are let into the tube at some distance from the ends, it is difficult to see how the distance between them is to be measured with the requisite accuracy.

Under these circumstances Lord Rayleigh preferred to use solid conductors, overcoming the difficulty of comparing the resistance measured with ordinary standards by a shunt method, which made it possible to express it at once in terms of the B.A. unit. The B.A. unit being thus found in absolute measure, a separate investigation of the specific resistance of mercury in terms of the B.A. unit completed the determination. Rowland and others have adopted the shunt method of Lord Rayleigh, which may be said to be an essential feature in the more probable determinations

\* Lorenz '0008    ...    '002.  
Rayleigh '002    ...    '004

by Lorenz's method. Spite of the conspicuous success which has attended the use of solid conductors by the shunt method, I venture to suggest a reversion to Lorenz's use of mercury. The physical constant to be measured is the specific resistance of mercury, and if this can, by direct measurement, be determined with accuracy, it seems inconvenient and undesirable first to determine the resistance of the B.A. unit in absolute measure, and then to determine the specific resistance of mercury in B.A. units. If consistently with accuracy the artificial B.A. unit can be dropped out of our experiments as well as out of the result; and the measurements made directly on mercury, the simplicity would seem to be a recommendation, and the argument is perhaps enforced by the consideration that there is very nearly as much divergence in the results of different observers for the specific resistance of mercury in B.A. units as there is in the values obtained for the B.A. unit in absolute measure.

The objections to the use of mercury in a tube are unanswerable; but the difficulties disappear if instead of placing the mercury in a tube, it is placed in a long trough, and if instead of measuring the distance between the two electrodes, one electrode is kept fixed while measurement is made of the distance moved through by the other between two equilibrium positions corresponding to two different rates of rotation of the disc. The latter measurement it is easy to make with accuracy, for the movable electrode may be rigidly attached to the movable headstock of a Whitworth measuring machine or some other measuring bank placed parallel to the length of the trough; and the two equilibrium positions may be taken near the middle of the trough so as to avoid danger of curvature in the equipotential surfaces passing through the electrode in its two positions.

Let  $n_1, n_2$  be the rates of rotation of the disc, and let  $l$  be the distance between the corresponding equilibrium positions of the movable electrode.

$$\text{Then} \quad M(n_1 - n_2) = \frac{l}{A} \rho$$

where  $\rho$  = the specific resistance of mercury.  
 $A$  = area of section of the mercury column.

But we are met by a new difficulty, the determination of the section of the mercury column. The capillary depression at the sides of the trough would make it a most serious task to determine the section by direct measurement to the required degree of accuracy.

Fortunately, this difficulty may be overcome by a further differential method, viz., by making observations with the mercury at two different heights in the trough.

Let  $b$  = the breadth of the trough;  
 $h_2 - h_1$  = the difference of height of the mercury surface in the two cases;  
and let  $A$  = the section of the mercury column when the mercury is at the lower position.

Then we have, denoting by dashed letters, the new values of the rates of rotation and the distance between the corresponding equilibrium positions—

$$M(n_1 - n_2) = \frac{l}{A} \rho$$

$$\text{and} \quad M(n'_1 - n'_2) = \frac{l'}{A + b(h_2 - h_1)} \rho$$

whence eliminating  $A$

$$\rho = \frac{M b (h_2 - h_1)}{l' - \frac{l}{n'_1 - n'_2} - \frac{l}{n_1 - n_2}}$$

It is assumed in the above formula that the sides of the trough in that part of it traversed by the movable electrode are plane, parallel, and vertical.

Hence the determination of the specific resistance involves the determination of:—

- (i.) Four equilibrium positions, two at each depth, with the rates of rotation of the disc to which they correspond.
  - (ii.) The breadth of the trough in that part of it traversed by the movable electrode.
  - (iii.) The difference of level of the mercury surface at the two depths.
  - (iv.) The coefficient of mutual induction of the coil and disc.
- The difficulties attached to the determination of equilibrium positions and the coefficient of mutual induction belong to all forms of Lorenz's method, whether the resistance measured is that of a solid conductor or that of a mercury column. Those specially incident to the use of a mercury column are:—
- (i.) The manufacture of an accurate trough, and
  - (ii.) The accurate measurement of the difference of level of the mercury surface in its two positions.

The trough used by me in the experiments of which I have spoken, was cut in paraffin wax contained in a strong casting of iron with its sides strengthened by outside ribs. The channel is approximately 43.5 inches long, by 1.5 inches broad, by 3 inches deep. It was first cut by a cutter rotating about 2,000 times a minute, attached to the slide rest of the College Whitworth Lathe, and subsequently finished by a scraper, attached in similar fashion, which took a very thin cut off sides and bottom. The result of the scraping was a very smooth and highly finished surface.

This method of obtaining a channel for the mercury was adopted in the hope that so cut in the lathe it might present a breadth constant to two or three ten thousandths of an inch. This hope was not realised: the results of subsequently calibrating the trough over the 10 inches of it traversed by the movable electrode indicated a variation of as much as .001 inch in its breadth. The objections to the use of paraffin wax are:—

(i.) Its softness makes it necessary to proceed with great care in measuring its breadth, lest damage should be done to the surface. This difficulty is satisfactorily surmounted in the form of internal callipers adopted in the calibration, which I must not stay to describe.

(ii.) The coefficient of expansion of paraffin wax is very large, its linear coefficient of expansion being about .0003. A change of temperature would, therefore, cause distortion in the wax channel seeing that the wax is enclosed in an iron casing.

We endeavoured to meet the danger of inaccuracy due to this cause by measuring the breadth of the trough as nearly as possible at the same temperature as that at which the electrical observations were made, care being taken to maintain the trough at a uniform temperature throughout the observations. During the month of the observations, the temperature inside the box in which the trough was placed, did not vary more than half a degree. But, notwithstanding this care, I am of opinion that the difference in the result of different sets of observations depends in the main upon variations in the trough due to varying temperature. But it is impossible to apply a correction, for paraffin wax is so bad a conductor of heat that its temperature could not be assumed to be that of the thermometers in the mercury channel; its temperature at any part would really be a function of ancient history.

Under these circumstances, I have come to the conclusion that I made a mistake in my choice of a substance; the disadvantages outweigh the apparent ease of construction. Probably a much more satisfactory result would be obtained by building up the trough of worked glass or scraped marble. I do not doubt that a sufficiently accurate trough might be made in either of these substances without straining the resources of the English mechanical engineer. We may observe that small errors become of less importance as the breadth of the trough is increased; and nothing but practical convenience limits the size of the trough we may employ, provided it is long enough in proportion to its breadth to make the equipotential surfaces plane over the part of it traversed by the movable electrode. It is further to be noticed that it is only the latter part of it that needs to be finished with the highest accuracy, and when the mechanical engineer has done his best, it is still possible to obtain a further approximation by a process of calibration.

The position of the mercury surface in the trough may be determined electrically by means of a pointed steel spherometer screw. The screw may be moved downwards until an electric circuit, comprising the screw and the mercury, is completed. It is of the utmost importance that the point of the screw should be kept clean, and that the mercury surface should be free from an oxide film, otherwise successive observations may differ from one another as much as .001 inch; but with clean mercury, if the point is carefully wiped with filter paper before making the observations, half a dozen observations may be without difficulty obtained, none of which differ from the mean by more than .00004 inch. To preserve the point, sparking at the mercury surface should be reduced as much as possible.

In order that the capillary surface should be of the same shape at both levels, the surface should always be brought to its measured position by pouring mercury into the trough, and never by taking mercury out of it.

I am of opinion that both the measurements to which I have referred as peculiar to the direct use of mercury by the differential method—viz., that of the breadth of the trough and that of the difference of level of the mercury surface—may be made with an

accuracy which will compare favourably with that which we can hope for in the determination of the equilibrium position; and, perhaps, also with that which we may expect in the measurement of the coefficient of mutual induction—measurements which are common to all forms of Lorenz's method.

Probably, also—though here I speak with hesitation and without experience—the accuracy will be as great as, if not greater than, that which attends the calibration of a glass tube, necessary to the determination of the specific resistance of mercury in B.A. units.

The electrical observations in Lorenz's method consist, fundamentally, in the determination of equilibrium positions, together with the rates of rotation to which they correspond. The equilibrium position is obtained when, if the direction of the current is reversed through the standard coil and trough, the reading of a galvanometer inserted in the disc circuit is unaffected. In the experiments I have made, I have found it best—following Lord Rayleigh—to take two sets of galvanometer readings for each equilibrium position, one set giving the change of galvanometer reading corresponding to reversal of the battery current for a position of the electrode slightly to one side of the equilibrium position; the other, the change of galvanometer reading, corresponding to reversal for a second position slightly on the other side of the equilibrium position. The galvanometer reading corresponding to the two positions of the commutator being called  $\epsilon$  and  $w$ , passage through an equilibrium position is indicated by a change in the algebraic sign of  $w - \epsilon$ . When  $w - \epsilon$  has been found for two positions slightly differing from one another, and including between them the equilibrium position, the latter may be found by simple interpolation. Since the readings,  $\epsilon$  and  $w$ , are not quite fixed, owing to small changes in the speed of the disc and variations at the brush contacts, it is necessary to take a number of reversals and to find  $w - \epsilon$  as the mean of the values obtained by combining the first value of  $\epsilon$  with the first of  $w$ , the first of  $w$  with the second of  $\epsilon$ , the second of  $\epsilon$  with the second of  $w$ , &c. The more quickly the reversals can be made to succeed one another, the better will be the results, for with rapid reversal variations in the position of the needle corresponding to no current through the standard coil (i.e., variations due to change at the brush contacts), are less likely to supervene. It is, therefore, best not to wait for the needle to come even approximately to rest after the disturbance due to the induction current on reversal, but to take the readings for the extreme positions in an oscillation, and having previously found the coefficient of damping, to calculate the position of rest from these two readings.

The whole difficulty in determining an equilibrium position arises from the want of constancy in the readings  $\epsilon$  and  $w$ ; and this want of constancy is due to two causes:—

1. Variations in the electromotive force at the brush contacts.
2. Variations in the rate of rotation of the disc.

It was with a feeling akin to despair that I watched the dance of the galvanometer needle during the first running of my apparatus, when the brush at the circumference of the disc was composed of a number of layers of thin phosphor bronze sheet controlled by a spring, and the dance continued, however well the circumference of the disc and brush were amalgamated at starting. Trials were made in the hope of improvement with amalgamated copper and amalgamated lead, and with the substitution of a dead weight pressure for the spring. But no satisfactory result could be obtained. It was noticed, however, that after amalgamation the readings were fairly steady for a short interval, and it occurred to me that if mercury could be continuously supplied to the surface of contact between the brush and the disc, this steadiness might be maintained. This led on to the idea of a brush consisting of a single wire perforated by a channel through which a constant flow of mercury might be maintained from a cistern of adjustable height; and a brush of this description was finally adopted. It presents very great advantages over any other form of brush tried.

Prof. Rowland used three brushes on the circumference instead of one, and I do not doubt that a multiplication of brushes is advantageous. Three or more such brushes as I have described, resting by dead weight pressure on the circumference of a disc ground true in place would, I believe, give an excellent result. The grinding of the disc in place is an important aid to steadiness of galvanometer reading.

It is to be noticed that the value of  $w - \epsilon$  for a position at a given distance from the equilibrium position is proportional to the current through the standard coil. Hence the small variations due to the brush contacts which do not at all depend on the current through the coil become proportionately of less importance as the current is increased. We ought, therefore, from this point of view, to use as large a current as possible. But the magnitude of the current is limited by the fact that it has to traverse the wire of the standard coil, which must not be made so hot as to risk the destruction of its insulation. This consideration points to the use of wire of considerable diameter in the standard coil.

If the wire of the coil is made of large diameter, attention must be paid to the influence on the coefficient of mutual induction of the non-coincidence of the current with the axis of the wire.

The second cause of want of steadiness in the galvanometer needle is variation in the rate of rotation of the disc; and this is the real crux. We are not helped in determining the equilibrium position either by increasing the sensitiveness of the galvanometer or the magnitude of the current through the coil, unless we procure a corresponding increase of steadiness in the running of the disc. We may increase the value of  $w - \epsilon$  for a position at a given distance from an equilibrium position in either of these ways,

but unless there is a corresponding improvement in the constancy of the disc rotation no advantage results, for the variations in  $w$  and  $\epsilon$  resulting from changes of speed are proportional to  $w - \epsilon$ . Hence in the construction of apparatus for a new determination mechanical engineers should be invited to do their very best to procure a constant rotation. No time or trouble spent in securing this will be lost for the purpose in view.

In my experiments the disc was turned by an electromotor directly coupled to it, and driven from a battery of secondary cells. Each bearing was fitted with sight feed lubricators, and a heavy steel flywheel was attached to the motor. The current passed to the motor through resistance coils, and could be varied continuously through a small range by a slide resistance of platinum wire, after the larger adjustment had been made to obtain a speed, approximately that which was required. A shunt worked by a lever also provided the means of taking out or putting in a small resistance suddenly, so as to allow the observer taking note of the speed to counteract small variations, due to alteration in the lubrication of the bearings.

To obtain improved steadiness, the chief point needing attention is lubrication. Some forced system of lubrication may be employed. Either oil may be pumped through the bearings, or they may be fed from a cistern placed at some height above them. Attention might also be directed to the friction of the brushes on the motor commutator. I do not think we can look hopefully to an increase of steadiness from the employment of any hand brake controlled by the observer, for the mischief is done, and the alteration has come about before he observes that it is his duty to put the brake on or off. In fact, the galvanometer needle picks up the alterations much sooner than the observer's eye. An electro-magnetic brake might be useful for adjusting the speed, but could not give any additional steadiness to the galvanometer needle. This can, I think, only be procured by perfection of mechanical workmanship, and increased attention to the truth of all rubbing surfaces, and their proper lubrication.

It remains to speak of the measurements necessary to enable the calculation of the coefficient of mutual induction to be performed. To facilitate an accurate determination of the mean radius of the standard coil, I desire to suggest that it should be a coil consisting of one layer of wire. The advantage in constructing a standard coil with a single layer of wire is that every part of it is visible, and that nothing is done to alter the position of the wire after measurements are made. If a coil consists of many layers, it is not quite easy to say where, after measurement, the lower layers go to under the pressure of the superincumbent layers. Lord Rayleigh found, in the case of certain coils used by him, that the mean radius calculated from measurements made in winding was greater by one part in 2,000 than the mean radius calculated from measurements made in unwinding, a result clearly due to the compression of the lower layers by the layers above them.

We should, therefore, expect that if the mean radius of a coil of many layers is calculated from measurements made in winding, it will be reckoned too large. In the face of this, it is interesting to note that in the measurements made by Lord Rayleigh by the method of Lorenz, the series in which the coils are so placed as to make the induction coefficient nearly independent of the mean radius, gives a result rather larger than the other series, which is what might be expected, if the mean radius is over-estimated. But the smallness of the variation (a little over one part in 10,000), seems to show that the error of mean radius must be very small for the pair of coils used by Lord Rayleigh. In general, we should expect as far as this cause goes, that values of the specific resistance in determining which coils of many layers are used would come out too low, since an overestimate of the mean radius of the coil means an underestimate of the coefficient of mutual induction. The apparent disadvantage of a coil of a single layer is that the number of turns will be fewer and, therefore, the coefficient of mutual induction of the coil and disc smaller than in the case of a coil of many layers. We may, however, in order to get a sufficient number of turns, make the coil of greater axial length than has been customary. But we cannot, in that case, use Lord Rayleigh's formula of approximation in calculating the coefficient of mutual induction. Under these circumstances, a new formula, applicable to a coil of moderate axial length, was a desideratum. Such a formula I obtained by

the direct integration of the expression  $\iint \frac{ds ds'}{r} \cos \theta$  for a circle and coaxial helix.

It is of the form

$$M = -8\pi n \frac{Aa}{A+a} \sum (-1)^m \frac{1.3.5 \dots 2m-1}{2.4.6 \dots 2m} \cdot \frac{1}{2m+1} \left( \frac{a}{A+a} \right)^{2m} P_m,$$

Where  $A$  = the radius of a circular section of the cylinder determined by the helix.

$a$  = the radius of the circle.

$n$  = the number of turns of the helix.

$2x$  = the axial length of the helix.\*

and

$$P_m = \int_0^{\pi} \frac{\cos 2\theta d\theta}{(1 - c^2 \sin^2 \theta)^{\frac{2m+1}{2}}}$$

\* *Phil. Mag.*, January, 1889. Read before Physical Society, November 10th, 1888.

when

$$c = \frac{2 \sqrt{\Delta a}}{A + a}$$

$r_m$  may be expressed in terms of  $c$ ,  $F(c)$ , and  $K(c)$ .

This is the formula I have used in calculating the coefficient of mutual induction of the coil and disc in the experiments already mentioned. The coil is of double silk covered copper wire of about .02 inch diameter, resting in a screw thread of .025 inch pitch, cut on a hollow cylinder of brass of about 21 inches external diameter. The axial length of the cylinder is something over 4.5 inches, and 185 turns of wire are wound on it. The disc has a radius of about 6.5 inches, and the coefficient of mutual induction is about 17,000 inches. This is a little more than a tenth of the coefficient of mutual induction of the coils and disc used by Lord Rayleigh in the first and second series of his experiments by the method of Lorenz, but it was found to be ample for the purpose in hand.

The mean radius of the coil was measured in the Whitworth measuring machine.

Uncertainty arose from two causes:—

- (i.) The silk covering of the wire;
- (ii.) The ellipticity of the coil cylinder.

The silk covering of the wire is of slightly varying thickness, and suffers compression to a varying extent during a series of measurements.

A standard coil, consisting of naked wire wound in a screw thread cut on a cylinder of insulating material, would be preferable to one of covered wire wound on a metal cylinder. There is, however, difficulty in finding a suitable insulating material. Wood immediately occurs to one's mind, but a large coil of wood, even though it be built up many pieces, is apt to change its shape with age and varying atmospheric conditions. But if a suitable insulating material, that can be turned true and that will retain its shape can be found, a single layer of naked wire in a screw thread cut on a cylinder of this material, would give us a coil the mean radius of which might be easily measured with certainty in the Whitworth machine to far more than one part in ten thousand.

The ellipticity of the coil cylinder deserves notice. The cylinder was turned with great care in the lathe already mentioned. It was cast with three lugs by which to bolt it to the face plate, and subsequently in precisely similar fashion to the strong brass frame which serves as its support during use. The first operation was roughly to fit the lugs to the face plate by filing. A roughing cut was then taken over the entire surface of the cylinder, so as to get rid of as much as possible of the internal strain due to unequal cooling of the casting. It was next unbolted and the lugs were carefully scraped to fit the face plate, and after again bolting it to the face plate the final turning was proceeded with. Very fine cuts were taken in finishing, and it was hoped that by these precautions we should secure a true right circular cylinder. Nevertheless measurements made in the Whitworth measuring machine show that the section of the cylinder at right angles to its axis is slightly oval. The longest diameter is 21.1056, and the shortest 21.0898, from which it appears that there is a difference of about .008 inch between the longest and shortest radius. It appears, indeed, to be a task of no ordinary difficulty to turn a cylinder of large size that shall remain true to the thousandth of an inch. Every fresh cut seems to alter its internal equilibrium, and after the cut is complete it adjusts itself to a new shape. The remedy lies in having a sufficiently massive cylinder carefully annealed to work on, and a fund of patience to make the requisite number of fine finishing cuts with a sufficient interval of time between them. In conclusion, the main suggestions I have to offer for consideration are the following:—

- (I.) That the time is ripe for a new determination of the ohm that shall be final for the practical purposes of the electrical engineer.
- (II.) That such a determination may be made by the method of Lorenz, the specific resistance of mercury being obtained directly in absolute measure by the differential method described.
- (III.) That the standard coil should consist of a single layer of wire, the coefficient of mutual induction of the coil and disc circumference being calculated by the new formula.

#### DISCUSSION.

Mr. SWINBURNE having suggested certain alterations in the moving parts of Prof. Jones's apparatus,

Lord RAYLEIGH said that he was very much interested in the paper. When he first planned observations by the method of Lorenz, he naturally cast about to see whether he could imitate him and deal as Prof. Jones had done, with an actual column of mercury. He found certain difficulties which at the time choked him off, and which Prof. Jones had overcome. He was quite conscious that good results might be obtained in that way, and it was of great interest to obtain them in that way. This was a distinct variation from the methods used by others. Here they had mercury brought directly into the absolute measurement. He was not quite sure whether he rightly understood Prof. Jones as to the manner in which connection with the mercury column was made. He thought as far as he did understand him, the movable electrode of which he spoke, was the one which actually carried the main current.

Prof. JONES said the current through the standard coil was introduced to the mercury by thick iron plates at the end of the open trough.

Lord RAYLEIGH thought that that arrangement commended

itself to them. What he attempted was as follows:—He took a closed tube of about 1 inch in diameter, and in order to get lateral connections he divided it, cutting it as clean as he could at two places into three parts, and then filing away a little bit of the edge, put them together with cement, leaving in that way the cavities through which the lateral wires could be introduced. He thought the amount of disturbance of the regular sections induced in that way was not much; and he was sure if it were gone into in a careful manner, good results would be obtained. Prof. Jones had used an open trough with a free surface in order to eliminate the effect of meniscus, by a differential arrangement of which the depth was varied. His only remark as to that would be that, as Prof. Jones explained it, it seemed to require four observations to get a result. That rather accumulated errors of reading, though not to a serious extent probably. He had very little doubt that by this method extremely accurate results might be got; and, no doubt, if Prof. Jones pursued the subject, he might obtain a degree of accuracy surpassing any yet obtained. He was not sure whether so high a degree of accuracy was very important at the present moment. No doubt they would like to get a greater degree of accuracy than they had obtained; but he was not sure that there were any other measurements with which that could be brought into comparison. Supposing they could, how could they use the number unless in comparison with other numbers obtained in other physical measurements? Nothing definite would follow from it, and if they used it for electrical purposes they had to face the difficulty of comparing wire with mercury. The only other point was as to the question of the temperature of the mercury. When a comparatively thin tube filled with mercury was used, there was no difficulty in immersing it in ice. Was the mercury in Prof. Jones's apparatus at zero?

Prof. JONES: No. 15.5°.

Lord RAYLEIGH: Then it depends upon the change in mercury.

Prof. JONES: Yes. The speaker went on to say that he used the formulæ of Mascart and Benoit.

Lord RAYLEIGH said that that correction could be made with a great degree of accuracy, but it took away from the method that consisted in the comparison. However, there could be no doubt of the very great interest of getting that result direct in terms of mercury without the inconvenience of any other standard, and he hoped Prof. Jones would pursue it.

Sir WILLIAM THOMSON mentioned one point as a source of error, viz., meniscus. Prof. Jones said that the meniscus was taken as the result of adding to the mercury in each case. If it was so finely balanced as that, he would be afraid that even tapping it during experiments would alter the level of the surface and induce error. No doubt Prof. Jones attended to that, but it was necessary to make quite sure that the error from meniscus did not sensibly vitiate the result, and if it did, by how much? As to temperature, he should think that its determination might be got with great accuracy by thermometers placed in the mercury itself at considerable distances in the parts subject to the differential test; two or three points at some distance from where the mercury was tapped would do. He was glad that Lord Rayleigh advised Prof. Jones to pursue the method which seemed, so far, exceedingly satisfactory.

Lord RAYLEIGH said he meant to have expressed his appreciation of the advantage of being able to reduce a coil to a single layer. No one who had measured a coil would doubt that. There was a question of the uniformity of the winding in the other direction—whether the windings were uniform along the axis? Prof. Jones said that they were laid on a screw throughout.

Prof. JONES briefly replied on the remarks made.

#### ON ALTERNATE CURRENTS IN PARALLEL CONDUCTORS OF HOMOGENEOUS OR HETEROGENEOUS SUBSTANCE.

By Sir WM. THOMSON.

(Read before Section A, September 5th, 1890.)

THIS paper consists of a description of some of the results of a full mathematical investigation of the subject which I hope to communicate to the *Philosophical Magazine* for an early number.

1. Two or more straight parallel conductors, supposed, for simplicity, to be infinitely long, have alternating currents maintained in them by an alternate current dynamo, or other electromotive agent applied to one set of their ends at so great a distance from the portion investigated, that in it the currents are not sensibly deviated from parallel straight lines. The other set of ends may, indifferently in respect to our present problem, be either all connected together without resistance, or through resistances, or through electromotive agents. All that we are concerned with at present is, that the conductors we consider form closed circuits, or one closed circuit; and that, therefore, the total quantities of electricity per unit of time at any instant traversing the normal sections in opposite directions are equal.

2. We suppose the period of the alternation to be very great in comparison with the time taken by light to traverse a distance equal to the greatest diameter of cross-section of our whole group of conductors. This supposition is implied in the previous assumptions of parallel rectilinearity of the electric stream-lines, and of equality of the quantities of electricity traversing, in opposite directions, the several areas of a normal section.

3. We farther suppose that the length of our conductors and

their effective ohmic resistances, are so moderate,\* that the quantities of electricity deposited on, and removed from, their boundaries to supply the electrostatic forces along the conductors required for producing the alternations of the currents, are negligible in comparison with the total quantity flowing in either direction in the half-period. This supposition excludes important practical problems of telegraphy and telephony, the problem of long submarine cables for instance, but it includes the problem of electric lighting by alternating currents transmitted at high tension through considerable distances, as, for example, from Deptford to London.

4. The general investigation includes as readily any number of separate circuits of parallel conductors, as a single circuit, but for simplicity in describing results, I suppose our system of conductors to be so joined at their ends as to constitute a single simple circuit of two parallel conductors.† It may be either two conductors or one conductor, one of which may or may not surround the other, as shown in figs. 1 and 2, representing cross sections. Each conductor may be single, as in figs. 1 and 2; or either may be multiple parallels.

5. We suppose each conductor to be homogeneous in substance and in cross section from end to end, but not necessarily homogeneous in different parts of the cross section. Thus the different

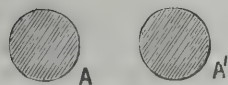

FIG. 1.

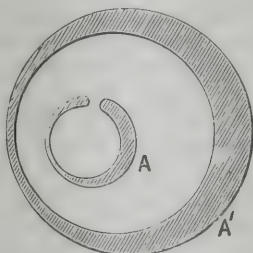

FIG. 2.

conductors, or the different parts of either, may be of different metals, or either conductor, or any part of either conductor, may consist of two metals (as iron and copper or iron and lead) laid parallel and soldered together.

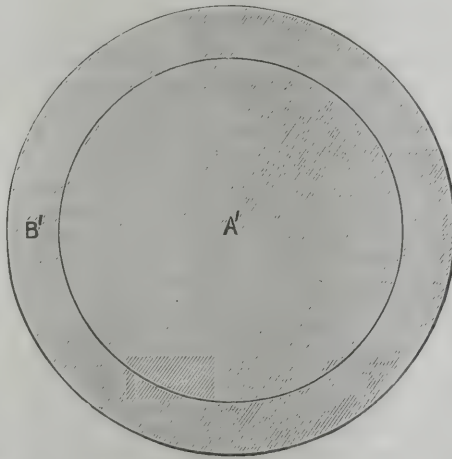

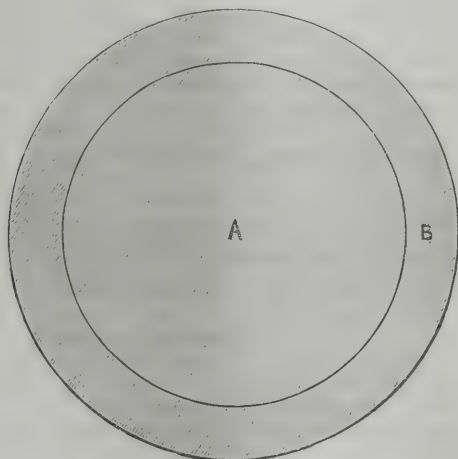

FIG. 3.

6. We shall call A and A' the cross sectional areas, or groups of areas of the two conductors, respectively, of the other. All the different portions of A are connected metallically at their two ends, and are thus all of them at one potential at one end and

\* The circumstances in which this condition is fulfilled may be usefully illustrated by considering the important practical cases of submarine cables, and of metallic circuits of two parallel wires insulated at a distance anything less than a few hundred times their diameter. For all these cases the numeric expressing the electrostatic capacity per unit length of either conductor (the other supposed for the moment to be at zero potential) is between 2 and 0.1, and for our present rough comparison may be regarded as moderate in comparison with unity. On this supposition the condition of the test requires for fulfilment that the mean proportional between the velocity which expresses in electro-magnetic measure the resistance of one of the conductors, and the velocity of a body travelling the length of the conductor in a time equal to half the period of alternation shall be exceedingly small in comparison with the velocity of light.

† The case of a single circuit made up of parallel conductors, so joined at their ends that to travel once round it we must go and come two or three or more times along separate conductors, joined by their ends in series, so as to make one circuit, is specially considered in my paper on "Anti-Effective Copper in Parallel or in Coiled Conductors for Alternating Currents," to be communicated presently to Section A.

another potential at the other end, and similarly for A'. The homogeneity of the material and of the cross sections along the length of the conductors, and the uniformity of the total currents assumed in Section 3, implies that all the different parts of A in one cross sectional plane are at one potential, even though A consist of mutually isolated parts, or A' consist of mere isolated parts. If, as in figs. 1 and 2, all the parts of A are in mutual metallic connection, and all the parts of A' are in mutual metallic connection, this would entail uniformity of potential through A, and uniformity of potential through A', even without the limitation of our subject laid down in Section 3.

7. The following are among some of the most noteworthy results of the full mathematical treatment of the subject:—

I. When the period of alternation is large in comparison with 400 times the square of the greatest thickness or diameter of any of the conductors, multiplied by its magnetic permeability, and divided by its electric resistivity, the current intensity is distributed through each conductor inversely as the electric resistivity; the phase of alternation of the current is the same as the phase of the electromotive force; and the current across every infinitesimal area of the cross-section is calculated, according to the electromotive force at each instant, by simple application of Ohm's law.

II. When the period is very small in comparison with 400 times the square of the smallest thickness or diameter of any of the conductors, multiplied by its magnetic permeability, and divided by its electric resistivity, the current is confined to an exceedingly thin surface stratum of the conductors. The thickness of this stratum is directly as the square root of the quotient of resistivity, divided by magnetic permeability of the substance in different parts of the surface, but the total quantity of the current per unit breadth of the surface is independent of the material, and, except in such cases as those referred to at the end of II, below, varies in each cross section in simple proportion to the electric surface density of the static electrification induced by the electromotive force applied between the extremities for maintaining the current. The distribution of this electric density is similar in all cross sections, but its absolute magnitude at corresponding points of the cross section varies along the length of the conductor in simple proportion to the difference of electric potentials between A and A', and is zero at one end in the particular case in which the conductors are connected through zero resistance at one end while the electromotive force is applied by an alternate current dynamo at the other end. On the other hand, the surface-distribution of

electric current is uniform throughout the whole length of the conductors, and it is only its distribution in different parts of the cross-section that varies as the electric density.

The proportionality of surface intensity of the current to electric density, asserted above, fails clearly in any case in which the circumstances are such that the distance we must travel along the surface to find a sensible difference in electric density is not very great in comparison with the thickness of the current-stratum. Such a case is represented in fig. 3, which is drawn to scale, for alternate currents of period  $\frac{1}{100}$ th of a second in round rods of copper of 6 cms. diameter. The spaces between the outer circular boundaries and the inner fine circles, indicate what I have called the mhoic thickness,\* being  $\frac{1}{714}$  of a centimetre for copper of resistivity 1611 square centimetres per second. The full solution for such a case as that represented in fig. 3, belongs to the large class of cases intermediate between I. and II., and could only be arrived at by a kind of transcendent mathematics not hitherto worked. But without working it out, it is easy to see how the time-maximum intensity of the current will diminish inwards from the surface, and will be, at any point of either of the inner fine circles, about  $\frac{1}{2}$  or  $\frac{1}{3}$  of what it is at the nearest point of the boundary surface; and that at points in the surface, distant from B B' by one-half or one or two times the mhoic thickness, the current intensity will be much smaller than it is at B B'.

III. In case I. the heat generated per unit of time, per unit of

\* Collected Papers, Vol. III., Art. CII., § 35.

volume, in different parts of the conductors, is inversely as the electric resistivity of the substance, and directly as the square of the total strength of current at any instant. In case II. the time-average of the heat generated per unit of time, per unit of area of the current stratum, is as the time-average of the square of the quantity of current per unit breadth, multiplied by the square root of the product of the electric resistivity into the magnetic permeability.

IV. Example of II.—Let the conductor,  $A$ , be a thin flat bar, as shown in the diagram (fig. 4),  $A'$  being a tube surrounding  $A$ , or another flat bar like  $A$ , or a conductor of any form whatever, provided only that its shortest distance from  $A$  is a considerable multiple of the breadth of  $A$ . The thickness of  $A$  must be sufficiently great to satisfy the condition of II., and its breadth must be a large multiple of its thickness. (For copper carrying alternating currents of frequency 80 periods per second, these conditions will be practically fulfilled by a flat bar of 4 cms. thickness, and 30 or 40 cms. breadth). The current in it is chiefly confined to two strata extending to small distances inwards from its two sides. (For copper and frequency 80 periods per second, the time maximum of intensity of the current at the surface will be about  $e^2$ , or  $7\cdot4$ , times what it is at a distance  $1\cdot43$  cms. in from the surface. The quantity of current per unit breadth, or as we may for brevity call it, the surface-density of the current in each stratum, is determined by the well-known solution of the problem of finding the surface electric density of an electrified ellipsoid of conductive material undisturbed by any other electrified body. The case we have to consider is that of an ellipsoid whose longest diameter is infinite, medium diameter the breadth of our flat conductor, and least diameter infinitely small. In this case the electric density varies inversely as  $\sqrt{(o B^2 - o P^2)}$ . The graphic construction in the drawing shows  $PQ = \sqrt{(o B^2 - o P^2)}$ , and we conclude that the time-

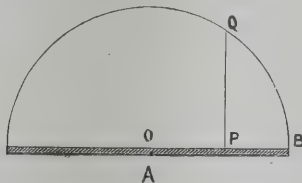

FIG. 4.

maximum of the surface density of the current varies inversely as  $PQ$ . The infinity which in the electric problem we find for electric density of the ideal conductor, is obviated for the electric current problem by the proper consideration of the rectangular corners, or the rounded edge (as the case may be), of our copper bar, which, though exceedingly interesting, is not included in the present communication. Suffice it to say, that there will be no infinities even if the corners be true mathematical angles.

V. Examples of cases I. and II.:—Let  $A$  consist of three circular wires,  $c$ ,  $l$  and  $i$ , of copper, lead, and iron respectively. In case I., the quantities of the whole current they will carry, and the quantities of heat generated per unit of time in them, will be inversely as their resistivities. In case II., if the centres of the three circular cross-sections form an equilateral triangle, the quantities of heat generated in them will be directly as the square roots of the resistivities for  $c$  and  $l$ ; and for  $i$  would be as the square root of the product of the resistivity into the magnetic permeability, if the magnetic permeability were constant and the viscous or frictional resistance to change of magnetism nothing for the iron in the actual circumstances. This last supposition is probably true, approximately, with a permeability of  $\frac{1}{100}$ th for iron or steel, according to Lord Rayleigh, if the current is so small that the greatest magnetising force acting on the iron is less than  $0\cdot1$  C.G.S.

VI. The dependence of the total quantity carried, on extent of surface, and on the solution of the electrostatic problem described in II, justifies Snow Harris, and proves that those who condemned him out of Ohm's law were wrong, in respect to his advising tubes or broad plates for lightning conductors, but does not justify him in bringing them down in the interior of a ship (even through the powder magazine), instead of across the deck and down its sides, or from the masts along the rigging and down the sides to the water. The non-dependence of the total quantities of current on the material, whether iron or non-magnetic metals, seems quite in accordance with Dr. Oliver Lodge's experiments and doctrines regarding "Alternative Path" and lightning conductors. The case of alternate currents is, of course, not exactly that of lightning discharges; but from it, by Fourier's methods, we infer main conclusions of II. and V., whether the discharges be oscillatory or non-oscillatory, provided only that it be as sudden as we have reason to believe lightning discharges are.

## DISCUSSION.

Prof. ROWLAND said that he had considered these alternating currents in parallel conductors, and he believed he gave a theorem with regard to the distribution in the case of perfect conductors. He thought that that was the only case in which the problem could be solved. In that case the distribution was exactly the same as it would have been if they had been charged with electricity at rest; and there was some theorem, which he had almost

forgotten now, with regard to the self-induction and the capacity. In that special case the self-inducting capacity. Of course, that was a much more limited problem than that Sir William Thomson had given, but he thought it led to interesting results. It guided them in their ideas with regard to the distribution, because in the case of perfect conductors the distribution of the current was exactly the same as the distribution of the density in the case of conductors at rest, so making the conductivity a little less than that; and they were guided to some extent by that theorem. He did not know that any solution had ever been obtained in the case where the conductors were not perfect, but Sir William Thomson, he considered, had found a solution of that nature.

## CORRESPONDENCE.

## Hysteresis.

I have not much to say about this subject, which is occupying many of our minds, but I must kindly be allowed to call the attention of those of your readers who are interested in the subject to a short but remarkable paper by Prof. Ewing in the *Philosophical Magazine* for this month; it is simply charming.

The manner of expression, and total absence of mathematical gas and turnpike roads, which is so often apparent in such work, is not only to the advantage of many who want the crop, but who cannot, for different reasons, follow the plough and harrow; but in other respects it is so highly suggestive, and so face-to-face in its experimental truth, that its effect upon intelligent readers must be more than ordinary; it is more than probable that from it they will learn more of magnetism than from their past digestion of tons of theories. I am glad Prof. Ewing has mentioned his line and fields of magnetic needles, and expandable base of rubber to shift their centres, the development of magnetic swing into "rotation," the lag explanation, and critical temperatures; but I will not go further, but promise everyone one of the finest scientific treats from a perusal of Prof. Ewing's latest magnetic contribution.

James C. Richardson.

P.S.—In the same number is an elaborate account all about glow-worms, which may also interest many who think we get too few light rays from our lamps.

## Electric Launches.

Much is often said of the advantages of electric launches, and comparisons are drawn between them and steam launches, to the great disadvantage of the latter. I have no particular partiality to the steam launch, and think it often a great nuisance to boating men on the Thames, but I am not aware that a great drawback to the use of some electric launches has been noted, namely, *the smell*. This, if present, has not been noticed by me in connection with the larger launches, but there is a small launch which may often be seen not 15 miles from London, which is a great sinner in this respect. In pulling down stream a few days ago, with the wind blowing towards me, I recognised the presence of this boat some hundreds of yards before reaching her, and remarked upon it to a friend who was steering; he said he could see nothing of her; but shortly after, we passed her towing a boat almost as large as herself. This nuisance is, of course, from the acid in the cells. I do not know what type is in use, but such a boat is a bad advertisement for the electric launch business.

FIRE RISK RULES.

"SUCH rules should be based on the deductions of experiment and the teaching of experience. They should give the utmost freedom of action and encourage progress. They should contain the minimum that is necessary, and this should be strictly enforced. Above all, these rules should be in accordance with the general principles which regulate all successful engineering constructions. For example, if we consider such familiar, but different structures as a locomotive engine, a steamer, or a bridge, we observe that there is no absolute safety in any one of them. Each has been perfected, not by directing the mind to a particular class of facts, but by a judicious compromise between many conflicting necessities, by giving neither more nor less than a just measure to each requirement, and in each case, all this has had to be done with due economy and limited means. In this spirit all fire insurance regulations should be framed."

This is the concise manner in which Mr. Wilson Hartnell summed up the requirements of fire risk rules and regulations when, before the British Association, he pointed out some much-needed amendments in those now existing ; and it is on his admirable paper, and the correspondence on the same subject in the *Times*, which has extended in a fitful manner over a period of some weeks, that we purpose offering a few comments. This, however, will not be so much with a view of suggesting any technical alterations, but rather from a desire to bring about the necessary feeling of compromise amongst the conflicting interests which now render the proper carrying out of electric lighting installations a matter of no small concern.

Mr. Hartnell condemns any attempt on the part of insurance companies to determine a fixed current density in conductors as "useless, vexatious, and scientifically wrong," and on this point we cordially agree with him, and would urge upon the various companies' technical experts not only the advisability, but the absolute necessity, of substituting for the clauses

dealing with the sectional area of conductors others based upon scientific principles.

When the subject of insulation is dealt with, it is not quite so easy to follow the ideas which presented themselves to the author's mind. That the chief object of electric light insulation is safety, and that this should continue for as many years as possible, is doubtless the view entertained by all electrical engineers ; but Mr. Hartnell seems likely to be misunderstood when he says that he considers durability of far more consequence than high insulation. The term "high insulation" is, of course, a relative one only ; but surely that very durability upon which so much stress is laid depends upon good and, probably, according to the material used, high insulation ? It, therefore, seems to us that Mr. Hartnell is in error in trying to dissociate the one from the other, although we concur in his opinion respecting the advantages of naked wires on insulators. So far as his distrust of vulcanised India-rubber goes, we would not like to say that it is entirely untenable ; on the other hand, evidence as to its superiority over all other kinds of insulation for electric light leads could doubtless be produced in abundance.

The question as to what wires will pass the insurance companies is perhaps the most vital point of all for the contractor, and a letter which appears in our correspondence columns is only one of numerous complaints of a similar nature which have reached us from many quarters.

So far as specifying the insulation resistance per mile is concerned, there should be no difficulty whatever in this, nor should the question of dry or wet weather enter into the matter at all. All wires covered with India-rubber, gutta-percha, okonite, Callender's bituminous compound, or what not, are tested after an immersion for a given time, usually 24 hours, in water at a temperature of, generally 75° Fahr. It is necessary, owing to the effects of temperature upon the insulating materials to reduce the dielectric resistance to a standard ; and in telegraph work, whether underground or submarine, it is always taken at 75°.

What the result of testing for insulation turns out to be after the installation is completed depends not so much upon the wire, which *per se* should be just as good as when it left the manufacturers, as upon the number and nature of the apparatus in circuit, which include lamps, switches, cut-outs, joints, &c., of various kinds. Naturally the wire, through lapse of time, will not remain in the same excellent condition as when first erected, for only under water will India-rubber and gutta-percha retain their insulating properties for many years unimpaired.

The controversy in the *Times* was commenced by Major Flood Page, who, in reply to a question as to the rules which were best to adopt for wiring houses in a small provincial town, answered that he could only say that some fire insurance offices followed one set of rules, others made their own, others had none, some trusted to inspection of each risk, and that, in the interests of the public, of the contractors, and of the offices themselves, it was most earnestly to be desired that one set of rules should be adopted by all the fire insurance offices.

Furthermore, this gentleman, after a careful examination of the rules of the Phoenix office and of the Institution of Electrical Engineers, and also of the special rules of ten different fire offices, concluded that they contained no crucial difference, nor any disagreement in principle, and, while founded on the Phoenix model, the variations were mere matters of detail, none of which, so far as the gallant Major could see, made the offices which introduced the changes any safer or better for the introduction. In conclusion, he advocated the adoption of Mr. Musgrave Heaphy's classical compilation on a variety of grounds, one being that "notwithstanding the number of years these rules have been in use, not a single instance of fire has occurred from any electrical installation placed up in compliance with them." Prof. Silvanus Thompson and Mr. C. H. W. Biggs took up the cudgels in the same cause; but two gentlemen, who have had much practical experience on a subject which their opponents could only treat theoretically, brought their guns to bear upon the Phoenix rules, and knocked them considerably out of shape, although not beyond recognition.

Mr. Verity explained how a serious effort was made to compile standard rules by the Institution of Electrical Engineers some time ago, but the rules then devised never commanded general respect and gradually lapsed owing to the action of certain fire-office surveyors, who throughout maintained that it was for them to satisfy themselves of the risks they took; that they were entitled to take whatever steps they thought necessary for the protection of their offices; and that they could not recognise rules laid down by an institution in no way associated with them financially in their risks. "But," says Mr. Verity, "it is distinctly wrong to say that electric light rules concern the fire offices only. They concern the electric supply companies, as they also must be satisfied with the efficiency of house wiring before they connect it to their system; they concern the electrical contractor, who could do his work more speedily and at a lower

rate if uniform-requirements were insisted on; and they greatly concern the house occupier who wants to be left in peace, feeling that when such work has once been done he will not be disturbed again. Besides the variety of rules mentioned by Major Page as being issued by fire offices, each electric supply company has also its own set of rules which must be complied with. It may be asked, Why should a supply company require rules also, and why is the fire-office inspection not considered sufficient? I fear the reply must be that although such inspection is often carefully made, yet in many cases it is very perfunctorily performed. Moreover, fire office inspection of electric work usually deals solely with the quality of material, the system of safety fuses, switches, &c., and it would be quite a novelty for any fire-office surveyor to be seen with instruments for accurately testing as to the efficiency of the work, and yet this is just what a supply company requires."

Mr. A. A. Campbell Swinton alluded to Major Flood Page's letter in a grimly sarcastic vein:—"Among persons competent to judge, there is now no question that, given proper appliances and good workmanship, the electric light is by far the safest of all illuminants, but, at the same time, it must be confessed that the statement that no fires have occurred where the Phoenix rules have been thoroughly followed is a very safe one, as it is, at all events, open to doubt whether there ever has yet been an installation carried out in entire accordance with these rules."

Both gentlemen are agreed that Mr. Musgrave Heaphy has undoubtedly been the means of bringing about the present high standard of electrical work, and his rules must form the basis of future work in this direction. But the objections that have been from time to time raised to the Phoenix rules are that they are too many and diffusive; that they leave too much to the discretion of the surveyor, whom, from the vast amount of work, it is impossible to so frequently consult; that some of the rules are unnecessary and not desired by other leading offices; and that some of the details required simply tend to unnecessary expense, without adding to safety.

Moreover, each edition becomes more and more voluminous, and this seems likely to go on *ad infinitum*.

It appears, therefore, that what is now desirable is a set of rules which will meet the approval of both insurance and electrical supply companies, and also the needs of wiring contractors. It seems on the face of it unnecessary that supply companies should require a set of rules for their own protection, but that this is at present the case is well known, and for obvious reasons they must themselves decide whether to supply current to a house or not, even if it has passed the fire office inspectors. The insulation question is a very important one for companies supplying on the low tension system, as a bad leak in one house may interfere with the supply of a whole district, a drawback which does not enter into the transformer method, so long as the primaries are kept free from the secondary coils. It will be readily seen then that although a fire office takes the risk of the house in which a conflagration

happens to occur, still the supply company has a heavy responsibility; this, however, might be merged into the insurance companies upon the adoption of new standard rules. Now, to effect this object, there is only one obstacle to overcome, and that is to bring Mr. Heaphy to take a reasonable view of the situation. He was in the beginning guide, philosopher, and friend to the electric lighting industry; now he is the stumbling-block.

A practical committee, composed mainly of men who have had the advantage of experience to guide them, is required, but it should not contain more than eight members, half that number representing the fire offices, and the others selected from the contractors and supply companies. More than these would lead to waste of time and quibbling, and in the end the result would, like Prof. Fitzgerald's famous mathematical paper, "An episode in the life of  $J = 0$ ."

Now we may take it that the fire offices are quite as anxious as the contractors to see one set of rules adopted, and, generally speaking, they will not care from whence they may emanate, so long as they fulfil certain conditions. No one wishes to deprive the "Phoenix" of the credit due to them in the matter, indeed, that would be impossible; but we and others have objected to Mr. Heaphy's rules as unsuitable from a business point of view, on account of their vagueness in important points, leading to unnecessary correspondence and interviews.

A very laudable attempt was made last year by the Fire Offices' Committee to issue an official set of rules which, we believe, would have given satisfaction to all concerned, but owing to the factious opposition of a few, it was deemed advisable to let the matter rest for a time, and thus we have drifted into the present unsatisfactory state of things.

Now as to an ideal set of rules. Let us consider them from the fire office point of view. In the majority of fire offices the inspection of electric installations forms but a small portion of the duties of their surveyors, and it is essential that that portion be rendered as light as possible. Hence rules regulating the installation of electrical energy should be definite and precise—in fact, in the form of *must be*, and not *should be*. Limits as to current, spacings, insulation, and the like, should be all clearly defined. Nothing should be left for "approval," and the "inspector" should be eliminated from them. It is quite possible, in our opinion, to draw up a set of rules that shall compel good work, without entering into minute details. Specify for enough copper, well insulated, and the proper jointing and carrying of conductors; state the principles governing the construction and mounting of switches and cut-outs; prohibit their being placed in positions where, if they go wrong, they can do harm; then, if the total insulation of an installation is satisfactory, we may rest content. Above all, do not harass the contractor with mere fads and fancies. Reasonable security against fire can be attained without unnecessarily adding to the cost of wiring, and thus retarding the more general introduction of what is, after all, the safest light to be had.

The insurance companies' task will in future be much simplified by the Board of Trade regulations. They need now concern themselves only with the house work. More latitude should be allowed in wiring off a direct continuous current supply, as against alternating transformer systems. With the former one well-known company had no trouble, whereas with the latter it has had a good deal.

The present agitation will do good, and we hope lead to some satisfactory results this autumn. Upon one thing, however, everybody concerned may rely. The leading fire offices will not have the Phoenix rules thrust upon them in their present garb—Prof. S. Thompson notwithstanding! Let that be clearly understood.

To bring the matter officially before the representatives of the fire offices, we would suggest a letter on the subject being addressed to the Secretary of the Fire Offices' Committee, Watling Street, from, let us say, the Electrical Section of the London Chamber of Commerce?

There is no need to trouble the Institution of Electrical Engineers further; there are certain broad principles common to all systems of electric lighting, but we feel inclined to agree with a gas contemporary that electricians will have to share the fate of gasfitters in a similar event, and meet every fresh case on its own merits. It cannot be a difficult task to settle the principal desiderata of safe electric light wiring; but exceptional cases are certain to arise from time to time, which cannot be dealt with by hard-and-fast rules. The project of employing the Institution of Electrical Engineers, or the Board of Trade, or any other outside body to draw up a code of fire rules, falls to the ground the moment it is perceived that since the Fire Offices would have to pay the damage, they must have the last word as to what precautions they would be satisfied with before issuing a policy.

A last word on the duties of inspectors. Can it be a satisfactory condition of affairs to know that the representative of a fire office may also be a consulting engineer even if he has no direct interest in any electrical supplies? We believe the inspectors of Lloyd's, for instance, devote the whole of their time to the duty of examining ships, and do not practise as technical advisers to the very people with whose vessels they may have to find fault. In electrical engineering, however, possibly because the business is yet but in its infancy, we have known instances of fire inspectors acting as censors of the work and materials advised by them, as experts, to be employed; and consulting engineers acting as contractors to their own clients; in fact, as they cannot fill up their time profitably in one branch, there is a tendency to combine all. These things should not be passed unnoticed, and the pages of the REVIEW are open to any of our correspondents to suggest plans by which the whole fraternity may yet become a happy family.

---

Refusal of a  
Concession for  
Electric Tramway.

THE Thomson-Houston Company has experienced a rebuff on the part of the Bremen Town Council. One of the reasons assigned for the refusal of the concession

for a projected line from the Rathhaus to the Buergerpark was said to be due to the very unsatisfactory working of the electric tramway at the Bremen Exhibition. The noise occasioned by the cars was considered unbearable, and another objection was raised against the sparks or "flashes of lightning" between the wheels and rails forming the return circuit. Similar complaints reach us from Italy anent another American system, and it appears that people on the Continent of Europe are not inclined to put up with nuisances which our American cousins tolerate. Toothed wheel gearing must sooner or later develop that rattling noise which, however natural to a machine shop, will never be appreciated in a public conveyance. Visitors to Blackpool are ever complaining of the noise occasioned by the electric trams, and these are fitted with the best kind of chain gearing, as are also those of Barking Road, with another noisy sort.

**The Oldest Electric Tramway.**  
THE Lichterfelde Electric Railway, the oldest in the world, has been extended to the Potsdam Railway station and opened for traffic.

**Duty on Electricity.**  
AMERICANS, more than any other nation, enjoy the privilege of paying duty for most things which cross their frontier. Hitherto electricity by means of submarine cables has entered free of duty; this was for telegraphic purposes only, but the probability is that this "imponderable matter" may, in future, be taxed if "imported" for other uses. There exists, according to the *New York Herald*, an enterprise called the "Cataract Construction Company," which has for its object the utilisation of the power of the Niagara Falls. This company having learnt that some Canadian parties are endeavouring to organise opposition for the construction of works on the Canadian side, with the intention of transmitting the power to the American side, have asked the Conference Committee on the Tariff Bill to insert a clause taxing the conveyed energy at the rate of \$5 per horsepower. It is not stated whether this is for a horsepower per minute or per annum; anyhow, the question is an interesting one, and we wonder whether the vigilant U.S. Custom House officials will stop the current at the frontier for the purpose of examining its *quality*, since the notion of two kinds of electricity still exists in certain quarters, or whether it will be passed through a meter kept by the excise officers?

**Paper Tubes for Underground Work.**  
PIPES for gas, water and electric cables, made of paper, have recently been exhibited in Vienna. The width of the paper is equal to the length of a given pipe. The paper runs first through molten asphalt and is rolled upon a mandril of wood, the size of which determines the inside diameter of the pipe. When cool, the mandril is removed, and the inside of the tube covered with a kind of enamel, the composition of which is kept secret. The outside is covered with a bituminous lacquer and sand. It is stated that a pipe of 2 centimetres thickness of material stands an internal pressure of 1,000 kilogrammes.

**Curious Reasoning.**  
AN electrical contemporary which, last week, devoted a leader to prophesying the speedy demolition of the B.A. for the Advancement of Science, unless reforms were adopted to meet the wants of the times, commences in the following contradictory manner:—"The afternoon of

Saturday was very fine in Yorkshire; and the meeting of the British Association may therefore be considered to be a success, since members had every opportunity for enjoyable excursions." Just as one swallow makes a summer, so a fine Saturday half-holiday sets the seal of success upon what the *Evening News and Post* calls a moribund association.

**Delay in Applying the Telegraph Scheme.**  
WE have already laid the general terms of the new telegraph scheme before our readers. Though some months have elapsed since its existence was made public, it is surprising to hear that it is not yet in general operation at the Central Telegraph Office. Whatever may have led to this extraordinary delay, it is to be hoped that such points as a fairer system of awarding sick pay to first and second class clerks, the question of a month's annual leave to the former body, and the unsettled question of the improvement of the position of senior clerks, will have been found to have received that full measure of recognition which their importance demand.

**Elmore's French Patent Copper Depositing Co., Ltd.**  
A FINANCIAL contemporary writing on this subject makes the following apposite remarks:—"The game that has been played is undoubtedly a clever one, but its success does not inspire us with confidence in the future of the companies. The mere fact that each parent concern has created sub-companies, and received substantial sums from them is sufficient explanation of the premium at which the shares of each of those concerns stand, but what has any one of them *earned*, and what have the off-shoots accomplished in the way of genuine business? It stands to reason that these fresh issues of capital cannot go on for ever. The time must come when the *bonâ fides* of each of them, and the commercial value of the Elmore process will be put to the proof, and it is our duty to keep this fact before our readers. Our own opinion is that the invention of the Messrs. Elmore is worth money, but not so much money as the wire pullers have obtained for it; not as many pence as they have been paid shillings, and we do not for one moment believe that the demand for absolutely pure copper is sufficient to return a dividend of 1 per cent. upon the capitalisation of the companies we have enumerated. Were there but one—Elmore's Patent Copper Depositing Company, for instance—it might be a pronounced success; but as it is, we feel convinced the result will be a disastrous one for the shareholders. It must be remembered that the aggregate capital employed is £820,020, made up as follows:—

Elmore's Foreign and Colonial	...	...	£120,000
" Copper Depositing	...	...	200,000
" Wire Manufacturing	...	...	300,020
" French Patent	...	...	200,000
			£820,020

To pay 10 per cent. upon that amount will require £82,000 per annum." It is possible, however, that Sir W. Thomson's paper to which we alluded last week on p. 287, may create a great demand for perfectly pure copper.

**Accumulator Trams.**  
How is it that with twelve cars the Birmingham Central Tramways Company run only five of them? Also how is it that the General Electric Power and Traction Company, with six cars at Barking Road, have only three and sometimes only two running?

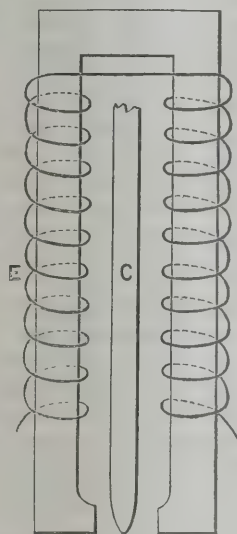

## ELECTRIC BLOW-PIPES.

By A. M. TANNER.

MY attention has been drawn to an illustrated article in the *Electrical World* of August 23rd, 1890, on welding with the electric arc. This article reviews certain inventions of C. L. Coffin on the above-entitled subject, and says that "the fundamental principle involved therein can be called that of an electrical blow-pipe;" furthermore, it is stated that the idea of handling the electric arc as one would a blow-pipe with a magnetic blast instead air, is certainly a very beautiful and ingenious application of theory. From this it would appear that Mr. Coffin, or the writer of the article in the aforesaid journal, is without knowledge of the electric blow-pipes of Werdermann and Jamin, and the fact that the action of electro-magnets upon the electric arc has frequently been studied, notably, by Quet (see *Comptes Rendus*, of French Academy of Sciences, Vol. XXXIV., A.D. 1852, page 805). Quet states that Davy was the first to experiment upon the voltaic arc with magnets, and that Despretz and others had also studied the same phenomenon. In referring to his own experiments, he says:—

"I caused a very powerful electro-magnet, made by Rhumkorff, to act upon the Davy arc, and I transformed the column of light into a long rushing point of an intense heat, and similar to the blow-pipe flame. I obtained this result by placing the carbons perpendicularly to the common axis of the electro-magnet coils. In order to explain my idea, I will suppose this axis to be horizontal, the carbons vertical, and their points placed between the neighbouring poles of the apparatus. In these conditions, instead of a vertical column of electric light a horizontal point is formed (dard) perpendicularly to the axis of the coils, just as when the blast of a blow-pipe is directed upon a flame. The analogy is so complete that, by reason of the noise produced by the arc, it appears as if some one were blowing. The light of this point has neither the whiteness or dazzling character of the electric column it displaces; nevertheless, its heat is very great, because it is capable of melting platinum. Because of this last-mentioned property, and the form taken by the arc, it appears to me that this kind of *electro-magnetic blow-pipe* can be usefully applied in the arts. The electric point (*dard électrique*) is remarkable for its length. In my experiments, it was eight or ten times more than the maximum length of the luminous column. Quet also states that the carbons can be placed at an angle, or one at the side of the other, in which case the electric point is formed laterally and parallel to the carbons. It will readily be perceived that Quet foreshadowed Coffin's process, in which the arc is formed between two converging carbon pencils and is blown downward upon the metal surfaces to be heated by the influence of an electro-magnet. An arrangement of parallel carbon electrodes (as in Jablokoff candle) and electro-magnet is shown by Richard Werdermann in his English patent, No. 1,438, dated April 24th, 1874, for a method of cutting rock or stone, &c. I can do no better than to quote the entire description of this patent, bearing upon an electric blow-pipe, particularly as the article on Coffin's welding process states that an air-blast is sometimes used for deflecting the arc. This is also an idea disclosed by Werdermann, as will be seen from the following abstract of the description found in the patent, viz.:—"When the rock is very hard, as porphyry, granite, gneiss, and the like, I prefer to use an electric blow-pipe. Fig. 3 is a plan of an apparatus for carrying this part of my invention into effect, and fig. 4 is a front view of the same. In this apparatus the carbon points, *g*, of the electric light are fixed on a suitable handle or frame provided with pinions, *h*, and racks, *h*<sup>1</sup>, to regulate their distance. I blow through the voltaic arc over the two carbon points, *g*, a powerful current of air or steam or other suitable vapour or gas. For this purpose I provide a carbon tube, *k*, arranged over the said

carbon points, *g*, and provided with an adjusting pinion, *l*, and rack, *l*<sup>1</sup>. The air, steam, or gas is supplied to the said carbon tube by a pipe, *m*. When the blast is in operation through this tube, and the light is burning, the flame of the voltaic arc will produce the effect of a powerful blow-pipe. *g*<sup>1</sup>, *g*<sup>2</sup>, are wires connecting the carbon points with a battery. In fig. 5 I have shown an apparatus in which the carbon points are arranged between the two poles of a powerful electro-magnet, and the blow-pipe is not used. As soon as the light is produced and the electro-magnet set in action, the voltaic arc is repelled and pointed like the flame of a blow-pipe. The heat obtained by the apparatus shown in figs. 3 or 5 is so intense that the hardest granite is thereby not only calcined but is fused in a few seconds."

E, Electro-magnet. C, Carbon pencil.

FIG. 5.

Another electric blow-pipe (*chalumeau électrique*) is described by Jamin in the *Comptes Rendus* of the French Academy of Sciences, Vol. 88, A.D. 1879, page 544. After having described an electric lamp with parallel carbons, and the effect of an electro-magnet upon the electric arc, first discovered by Quet, Jamin states:—"The fusion of lime proves that the arc thus projected by a magnetic effect is capable of considerably heating all bodies; it is a genuine blow-pipe, and probably the most powerful of all. I recommend it to chemists and physicists."

The blow-pipes of Werdermann and Jamin, although not specially designed for such purpose, are adapted to be used for the electric welding of metals, since they have parallel electrodes arranged in such a way that the arc can be projected upon surfaces placed beneath the arc. There is another more recent reference to be considered which is also an electric blow-pipe, and is specially designed for welding and soldering metals. The English patent of Bernardos and Olszewski, dated October 28th, 1885, No. 12,984, describes and illustrates in figure 35, an "Electric Solderer," which has two parallel carbon pencils fastened in a holder and arranged above an anvil on which the work is placed. The anvil is surrounded by a wire coil, so that when the electric current produces the arc between the parallel carbons and flows through the anvil coil, the anvil is converted into an electro magnet "whereby the flame of the arc is drawn to the object to be operated upon."

I think I have satisfactorily shown that Mr. Coffin did not invent the electric blow-pipe. Quet having fused platinum with a so-called "electro magnetic blow-pipe" in 1852, and Werdermann having subsequently applied the same instrument to the cutting and fusion of mineral substances. Du Moncel, the eminent historiographer of the applications of electricity, says in his work: "I desire to be impartial in my

writings and 'à rendre à César ce qui appartient à César.' It is well that this should be observed in this modern age of electricity, and credit bestowed where credit is due.

### MUNICIPAL LIGHTING.\*

By M. J. FRANCISCO.

THE electric spark that Franklin gathered upon his key lay dormant for years, until from the fires of genius, guided by the finger of science, there flashed forth the electric light. This has been increased and magnified, until to-day America stands as the exponent of this science, with 300,000 arc and 4,000,000 incandescent lamps flashing like meteors across the continent. Thus has science aided nature in lighting up the streets and highways of our native land, from the shores of the Atlantic, across the snowy peaks of the Rocky Mountains, to the golden shores of the Pacific.

This vast industry, requiring an army of over 300,000 men and an investment of \$300,000,000, is the result of American genius and enterprise. Truly we may well congratulate ourselves that we are here to-day as the representatives of this science and industry, which is revolutionising the world. Not only has the globe been encircled with telegraph symbols, and the human voice sent flying across space for thousands of miles, but the ocean itself has been studded with electric lights, guiding the mariner across its waste of waters, and flashing its brilliant hues as a welcome beacon upon the weary eyes of many a watching crew, whose vessel was sinking in mid-ocean.

This science, fraught with so much good for mankind, which has put millions of money into circulation and furnished employment to thousands of labouring men and others, is now menaced by men who, posing as economists, desire to use this power for political and other purposes, as well as for their own aggrandisement, regardless of the interest of the masses or the public welfare. The plain English of this movement is municipal control of electric lighting plants.

Who are the great apostles of municipal ownership of electric lighting plants, claiming that municipalities can furnish lights cheaper than private corporations? Mostly visionary, theoretical dreamers. Not one has had a single day's practical experience in the electric lighting business. For example we were treated to a specious article in the *New York Independent*, purporting to come from a professor of Johns Hopkins University. An examination of the article shows at once that the author has no experience or practical knowledge of the business, and proves to be simply a youth from Omaha, Neb., who has been studying there for a couple of years. He is now told to cry monopoly, and this article is the result. These are the persons who are being used by professed economists, wire-pullers, and others as figure-heads; who make statements based upon a state of things that do not exist, and use such statements in contradiction of the actual experience of practical men and the best scientists of this generation, who have not only made the subject a study, but demonstrated the same by testing it every night for years.

If a municipality can sell electricity cheaper than private corporations, why should they not manage all other industries and trades of the country? All cities have large amounts of printing done; why not have the city own and run paper mills and printing offices? also street cars, and own mines and sell coal? They also use immense quantities of stone, building material, &c.; then have them run a marble quarry. The taxpayers use carriages; let the city build these also. And so on with every industry requiring the investment of private capital. If municipalities can save the taxpayer

money in controlling and manipulating one industry, why not all? If they can do it cheaper, then every taxpayer would receive the same proportional benefit as is claimed for electric lights.

The great argument used in support of municipal control of lighting plants is a list of cities, with what purports to be accounts of the cost of their electric lights, where over half of the expense of the lights has been charged to other departments. Among these are Bay City, Bangor, Dunkirk, Chicago, Ypsilanti, Topeka and Lewiston.

We will examine a few of the claims made as to the cost of lights in these cities.

The City Superintendent of Bay City, Mich., reported that the cost of the electric lights was only \$40 per year. The Council of Bay City appointed a special committee to investigate the expense of city lights, and they submitted a report showing that the city was running 137 lights at a cost of \$59.42 each per year, not including taxes, water rates, interest or depreciation. Including interest, 5 per cent. on \$35,000, cost of plant, taxes and water rates,  $2\frac{1}{2}$  per cent., 10 per cent. depreciation, the cost was \$104 per year each lamp, running only dark nights. A short time since, during a thunder shower, the city was left in darkness, because the City Superintendent was afraid of burning out an armature if he ran the lights. A gentleman passing an evening in Bay City recently inquired why they did not have street lights, and the answer was "We do have them," and sure enough, at nine o'clock, they started the lights. Still, the price charged by electric light companies for first-class service, with lights every night, even when obliged to compete with the rival forces of Heaven's batteries, is compared with such service as shown in Bay City.

The city of Bangor claims that the average cost of burning a light each night is  $12\frac{3}{4}$  cent.; that is \$46.23 per year for each lamp. The electrician is paid \$78.50 per month, or \$942 per year; his assistant receives \$520 per year; one lineman is employed at \$624 per year; two trimmers at \$1,248 for the year—making \$3,334 for wages of these men, being \$22.82 per lamp per year. They run all night, requiring double lamps and four carbons for each and every day, calling for 1,460 carbons per year each lamp; for these they pay \$13 per thousand, and in addition pay 96 cents. per thousand for freight and 5 cents. per thousand for cartage from the freight-house, making cost of carbons \$14 per thousand, or \$20.44 per lamp per year. Allowing \$2.97 per year for oil and waste, we find the amount paid by the city for wages, carbons, oil and waste was \$46.23 per lamp per year. This is  $12\frac{3}{4}$  cents. per lamp per night, just what is claimed as the entire cost to the city for running their lights. The plant cost \$35,000, and this does not include anything for the water-power nor for any portion of construction of the dam or cost of its maintenance, or for the station buildings. Interest on \$35,000 at 6 per cent., \$2,100; depreciation on electric apparatus, 10 per cent., \$3,500; broken globes during the year, \$130; wall controller burned out, costing \$160; 15 lamps broken, repairs costing about \$300; damage to mast-arms, repairs costing \$100; repairs at station, \$500; also \$730 paid for coal. Here is \$7,520, which is part of the expense of the electric lights charged to some other department, while to get the true cost there must be added to this the repairs to the dam, interest on the cost of the buildings, wages of an engineer when engine is used, cost of new brushes and segments; also taxes and water rent, which the city would receive from a private corporation if running the lights, which, at the lowest estimate, would be over \$1,000 per year; thus making a total cost to the city of \$15,271.86 for running 146 lamps one year, being \$104.59 per lamp, and that, too, with water power all the time except for about six weeks.

The favourite place quoted by advocates of municipal ownership is Dunkirk, N.Y. I herewith give the report of the water commissioners of Dunkirk. As a specimen of expert bookkeeping, and a sample of the way accounts are kept by cities, I recommend the plan

\* A paper read before the American National Electric Light Association, August 20th, 1890.

to all electric light men ; for, if you are endeavouring to satisfy your constituents or stockholders that electric lights can be run without money and without price, it cannot be excelled. The report reads as follows :—

“PAID ON ACCOUNT OF ELECTRIC LIGHT.

For linemen's salary ... ..	\$540.00
For fuel ... ..	933.24
For supplies ... ..	447.60
For labour repairing line ... ..	41.42
For repairs on engine and boiler ... ..	65.64
For repairs on machinery ... ..	99.40
For miscellaneous accounts ... ..	14.60
	<hr/>
	\$2,141.90

“The above statement shows very distinctly that the most sanguine predictions as to the cost of running the electric lights of this city have been more than realised. After a trial of one year and eight months, the machinery and line are in better and more perfect condition than when first started. The cost of our electric light does not exceed 1 cent per hour for each light.”

Here we have a report from the city authorities stating that the entire cost to the city of running 55 arc lights one year was \$2,141.90.

You will notice one item is repairs on engine and boiler ; also one item for fuel, showing that the plant was steam power, and, what is far better, a style of boilers and engine that ran the entire year, starting and stopping at proper times automatically, without anyone to look after them except a man occasionally to make a few repairs—the coal walked into the furnace without assistance, and no one was employed in or about the station, neither did the plant cost the city anything.

Here is a sample of the reports made by politicians and those professed economists, which shows just how reliable they are. Of course, a man of practical experience, and knowing that electric lights do not run without human agency, would look further before accepting such a statement ; and when we examine the accounts of the water-works, we find engineers and firemen paid \$3,555, supplies \$449, general expenses under superintendent \$995, miscellaneous accounts \$240, superintendent's salary \$720, interest on bonds \$7,025—making \$12,984 additional. Even if only one-third of this is charged to electric lights, we have \$4,328 to add to the \$2,141, making \$6,469 for 55 lights, or \$117 each per year. Consistency, thou art a jewel !

Chicago, it is claimed, is the centre of the world, and the only place on this mundane sphere where mortals can be happy, and where life can be spent without thought of money or the hereafter, because their electric lights only cost \$73 per year. We admit that Chicago has triumphantly secured the World's Fair, and is now transposing our national air to “Hail, Chicago ! happy land.” But they have not yet seen the bills for the electric lights, as furnished by the city and used on that occasion. When they do, the city electrician will need to add something more to his stereotyped answers that the cost of city lights “does not include any expenses such as you mention—taxes, water rent, interest on investment, insurance, repairs, depreciation or renewal of plant in general ;” neither will it be expedient to charge the wages of the electric light linemen to the fire alarm telegraph department, notwithstanding it works very nicely now, and helps wonderfully to make the cost of an arc light appear small.

Upon investigation of one of their stations of 275 to 300-light capacity, I find that the chief engineer receives \$1,200 ; assistant, \$1,030 ; four firemen, \$2,880 ; six trimmers, \$3,240 ; line tester, \$720 ; three linemen, \$2,520 ; cost of carbons, \$3,800 ; fuel, \$12,000 ; interest, \$14,000 ; depreciation, 2½ per cent., \$8,750 ; oil, waste, repairs, globes, taxes, &c., \$7,000—making \$57,190 a year expense for running 300 arc lamps, being \$190.63 per year per lamp, and this makes no provision for salary of electrician, superintendent, or for armatures burned out, or any accidents or

damages. With the linemen's wages charged to the fire alarm telegraph department, we can reduce this \$2,520. Now, to what other department do they charge the other expenses to reduce it to \$73 per year per lamp.

Ypsilanti, Mich., is the Mecca toward which all advocates of municipal ownership turn their longing eyes, and we are informed that the entire cost of a 2,000 C.P. lamp is \$23.61 per year, when the truth discloses the fact that Ypsilanti pays \$72 per year, only running 18 nights a month until midnight. Wishing to have the views of the prominent authorities of this wonderfully-managed city, the following questions were propounded, and I give both the questions and answers :—

Q. 1.—With your experience, are you in favour of cities doing their own lighting ?—A. No.

Q. 2.—Why ? A.—Political preferences and frequent changes of management are too expensive. Incompetent engineers, linemen, and trimmers kept in place by a committee for political or other purposes ; poor carbons, lack of attention generally, grounding of wires, breaking of globes, infringement of patents, constant repairs, &c., make this system expensive and an unknown amount till the year expires. *The wear and tear is immense*, all kinds of complaints and no responsible head is the rule. On the contract plan for light you pay for what you get only, and know what to provide for in the estimate for tax levy.

Q. 3.—If your city had the work to do over again, do you think they would do the same ?—A. No.

Q. 4.—Has the municipal operation of your plant met all expectations and requirements ?—A. No.

Topeka is another place where electric lights furnished by the city are cheaper than sunlight, and the city jubilant over their purchase. I quote from a letter written by a prominent official of the City of Topeka, which seems to prove that their millenium has not yet arrived. He says : “The agreement for all night lighting was \$6 per light per month. We find that the cost of operating the plant of 184 lights for all night has been \$11 per month. The agreement further provided that lights should be 2,000 candle-power ; all the tests we have made do not show them to be over 500 candle-power. Our lights so far have been very unsatisfactory. My own opinion of the matter is that it would be much cheaper in the end for the city to have contracted with some of our electric light companies here to furnish the city with its lights at so much per light. We would then have known at least just what they would have cost. As it is, we have to take our medicine, which is liable to be a very expensive dose. It is a very expensive luxury, and there are so many expenses coming up that we cannot foresee ; therefore, I say, when you take everything into consideration—interest on the investment, wear and tear on machinery, dynamos, &c. (the contractors are already building over ours, and they have not run two years yet)—consider well before contracting for a plant.” Here is the opinion of an honest official, who has had experience with a city owning a plant.

Lewiston, Maine, is another brilliant example of municipal ownership. They have a plant of 100 arc lights, which cost the city \$15,000. They burn, on an average, 24 nights per month on moonlight schedule, and the Mayor says the actual running expenses are \$4,200 per year. Add interest on cost of plant, depreciation, 5 per cent., taxes, rent of water-power, which the city would have received from a private company ; therefore it is costing the city for 100 arc lights, using water-power, \$7,200, or \$72 per lamp per year, while the local electric light company offered to furnish the same lights for \$5,760, being \$1,440 less than it costs the city to run their own lights ; and still it has been advertised broadcast that the cost of arc lights in Lewiston was only 14 cents. per night.

I have secured reports from fifty municipal plants, embracing nearly all the cities and towns in the United States owning plants, and find that the cost of these has been \$1,511,225 ; that they are using 3,725 lamps ; 12 places running all night, and 38 until midnight or

on the moonlight schedule ; that the average price paid for coal is \$2.34 per ton ; that the actual running expenses have been \$251,194 ; that the interest on the cost of these plants is \$90,691 ; depreciation at 5 per cent. \$75,576 ; cost of replacing armatures actually burned out, \$12,000 ; taxes city would have received from private corporations if they had furnished the lights, \$15,715—making the total expense to these 50 cities of burning 3,725 lamps (two-thirds of them only until midnight) for one year \$444,486, or an average cost of \$119.24 per lamp per year. In the figures going to make up the cost of plants and the running expenses I have taken the statements and amounts as given by the city officials, but when we are told that the total amount paid for a complete plant of 68 arc lamps, with engines, boilers, dynamos, &c., was only \$1,300, and informed that the total running expenses of a plant that cost \$12,000 are only \$1,100, and in the same communication the statement is made that they pay their engineer and linemen \$125 per month, making annual bill for these men's wages of \$1,500, we naturally long for the secret which enables them to settle this amount and pay for repairs, oil, coal and other expenses with an expenditure of only \$1,100.

I have statistics from 365 electric light companies furnishing 35,100 arc lamps for street lighting, three-fifths burning their lights all night, and two-fifths burning until midnight, or on the moonlight schedule. The average cost of coal is \$2.76 per ton. The average price charged per lamp for street lights is \$118 per year. This is the price when furnished by electric light companies, who have assumed all the risks and liabilities incurred in the business, and who must furnish first-class lights. This is the cost with lights burning every night without a break, as the contract calls for, and necessitating a rebate if lights are out, which would reduce the price paid by the city.

Only one-third of the cities owning plants run them all night, while of street lights furnished by private companies three-fifths burn all night. Lamps all night and every night would burn 4,000 hours per lamp, while the moonlight schedule would only require about 2,100 hours per lamp. The cost to companies, of course, is much more for all night lights than it is until midnight, and had lights run by municipal plants been burned the same length of time as lamps furnished by private corporations the average cost would have been still more, as lights must have burned about twice as many hours.

It will be noticed that the average cost of coal used by municipal plants was \$2.34 per ton, owing to the fact that the majority were located near the mines or places where coal was cheap, and the average as shown for electric light companies is \$2.76 per ton, owing to the fact that coal was transported long distances, at high rates of freight. Even with this factor against them, it shows conclusively that private corporations are furnishing cities with lights for less money than they can themselves produce them while owning the plant. This, too, with the expense of operating city plants figured as given by the various cities, which their own report shows is incorrect, and less than actually paid.

It is well known that if a private corporation is furnishing municipal lights, when they are out for a short time or are not up to standard, a rebate has to be made, amounting in the aggregate to many thousands of dollars ; but you will never see this item deducted when advocates of municipal control are quoting the cost of lights. Neither do they allow the fact of the city's liability for damages and accidents to be developed. If the municipality own the plant they assume these chances, and here is a feature of responsibility which in most States rests upon the individual as well as the city. The property of any citizen can be held for an execution against the town for injuries caused by a municipal plant, no matter if it amounts to thousands of dollars, and thus he might be deprived of his most valuable personal rights and liberties. If electric light companies furnish the lights, they must meet such claims and protect the city from loss, and

the court records show that electric light companies have paid heavy damages on this account.

In the reports received from city officials regarding the cost and operation of their lights, one says : "No expenses charged to lighting account." Again : "Lights are not started for an hour after dark." Many say : "Whenever a thunderstorm approaches, lights are shut down and city left in darkness." Another says : "Have not had lights for past two weeks, owing to some trouble at station ;" while many report wages of *employés* charged to water department, and others that no account of lighting expenses is kept. Here we have the basis upon which reports are made that the cost to cities owning plants is so much less than it is when private corporations furnish them, simply deceiving the taxpayers by charging part of the cost to other departments, while raising a hue-and-cry about the extortion of electric light companies.

No sane or fair-minded man will, with the corruption and fraud practised by politicians at the present day, attempt to prove that it is for the best interest of the taxpayer to place faith in the honest or conservative management of any enterprise which can be manipulated in the political arena for the advancement of the men in power. The histories of New York, Philadelphia and many other cities are samples of such methods and their purifying effects upon politics. Hypothesis and theory may do on paper, but actual results obtained by practical application and experience are the only reliable data upon which to base any statement relating to the cost of street lighting. In every case these have shown, where all the facts are given, that it has been for the best interest of the citizens and taxpayers to contract with an electric light company for lighting the streets of any city.

Many cities have found by actual experience, after spending a large amount of money, that this is a fact. The City of Greenville, S.C., has sold out its municipal electric lighting station, the purchasers agreeing to relieve the city of all pending liabilities in connection with the light plant. The city has agreed to pay \$100 per year per lamp for not less than 40 ; the agreement to run for 15 years. Negotiations are pending in several other cities for a sale of their plants to the local or private electric lighting company, as they have found that it was impossible to produce the light, when managed by politicians with no interest in the business, as cheaply as could be done by a private corporation whose managers were financially interested in its success.

There is another feature of this business that it is well to consider. Under the authority and sanction of the Legislatures of the States, private capital amounting to millions of dollars has been invested in the enterprise of electric lighting. The benefit that municipalities have received from this capital is enormous, and it is a question whether the private capital thus locally invested under the sanction of the State can be jeopardised and endangered by the action of municipalities, who are subject to and under the control of the State. In England this matter is fully settled, and no municipality can operate its own plant, if by so doing it will interfere with any local or private company authorised by Parliament.

Judging the future by the past, with the mighty strides that have been made in electrical inventions, two years from now the entire apparatus at present owned by municipalities may be consigned to the scrap pile, and necessitate a new outfit costing thousands of dollars. What is to be done in this case ? Levy another tax or issue more bonds, and thus load the city with more debts. Electric light companies have already had this experience, and I can cite a case where the company paid \$4,500 for their dynamos, and, after a little over two years, could only realise \$300 from those same machines. Why is this ? Simply that improved plans and apparatus have been discovered which reduces the cost of producing electricity, and unless companies can control these new patents they will be stranded in the race of invention.

Consider, then, for one moment the effect upon the

business world if to-day it were possible to blot out electricity and electric lights, with all their conveniences, comforts and luxuries; to stop the progress and development of this wonderful science, and shroud America in a gloom that could only be expressed by Byron when he "had a dream which was not all a dream," and

"The bright sun was extinguished,  
And morn came and went—and came—and brought no day,  
And all hearts were chilled into a selfish prayer for light.  
The rivers, lakes and ocean all stood still,  
And the clouds perished. Darkness had no need  
Of aid from them—she was the Universe."

### THE RELATIVE COST OF GAS AND ELECTRICITY IN COTTON MILLS.

WHEN it is attempted to draw comparisons between gas and electricity and their relative cost, it is not unusual to estimate the former by simply referring to the actual cost of the gas consumed as registered by the meter, whilst the cost of an electric light is obtained after every possible charge has been put down to its account. Such a result not infrequently places the electric light at a serious disadvantage from the economical point of view.

But an estimate of this character is far too one-sided to give a true statement of the case. Those who are interested in the electrical industry do not object in the least to have the electric light properly debited with all the incidental and necessary items, but they do naturally object that, on the gas side, all the incidental items, save that of actual consumption, should be omitted. Neither is it fair altogether to omit from these calculations the relative benefits, or otherwise, derived from the use of the two illuminants.

As we have remarked, an electric light installation is debited with all its charges to the capital account, and in its maintenance not only is the depreciation of the plant considered, but every item due to repairs, wages, &c., is fully considered and provided for.

On the gas side, however, no such items are usually taken into account; but, dealing with the gas question in a large mill or manufactory, there are a number of expenses necessarily entailed, which should certainly be taken into account when a perfectly true and reliable comparison is desired. For instance, the installation of a gas plant of 1,000 or more lights into a large mill entails the expenditure of a considerable amount of capital, although it is known that a gas plant can be put in at the present time for a very small sum. There are, however, many mills where the capital expended upon the gas installation has cost 20s. per light, whilst at the present time they can be installed for as low as 5s. or 6s. per jet. Still, this requires some capital, and, necessarily, should be subject to some charge for depreciation. The lighting up of a large mill, and the extinguishing of these lights requires a considerable amount of labour and time. The value of wages taken up per annum in this alone is a serious item, but it does not count. It will be found that where there are a large number of lights in use there is almost always a "gasman" employed in looking after the fittings, and keeping everything in proper repair; but his wages are not counted, nor are the various items which usually come under the head of repairs, for it is impossible to conceive that gas-pipes and fixtures are never out of order.

When the relative charges are properly considered, a more reliable estimate can therefore be obtained; but there are circumstances which prevent such a comparison from being made; this is owing to the fact that it is very rare for the cost of the maintenance of an electric light installation to be kept. We are aware, however, of several cases where this has been done, and we have had the following statement presented to us for publication, which gives the information in a comparative form, prepared by the proprietors of some very

large mills in the neighbourhood of Manchester. These results give the relative cost of gas and electricity for a period of six years, taken from the actual working experience of one of the company's mills at Mosesgate, near Bolton. The statement is given exactly as handed to us.

HORROCKS, CREWDSON & CO., LIMITED, BOLTON.

Cost per light per annum—Gas, 5s. 6½d. — Electricity, 4s. 0½d.

Gas costs 38·34 per cent. more per light, and (as one electric light displaces two gas lights in weaving shed), gas costs 176·68 per cent more per loom.

It will be observed that, in the foregoing statement, the gas account is simply debited with the average gas consumption and a depreciation charge of 5 per cent. upon the original cost, nothing being allowed for repairs and such other charges as we have previously mentioned.

The account for the electric installation of 263 lights includes dynamos and everything that is necessary to a complete plant. The work in this case was satisfactorily done by the Manchester Edison-Swan Company, Limited, and it is gratifying to notice here that, throughout the six years, the working has been of a satisfactory character. The charge for depreciation is 7½ per cent., or one-half more than in the case of gas. The power of the steam engine is estimated at 30 I.H.P., that being the proportion of the main engine of the mill, utilised for the purpose of driving the dynamo. Tests subsequently made showed that the actual I.H.P. utilised was only 27 H.P., and at this figure the coal consumption has been calculated. The item for repairs, &c., includes the cost of oil and sundries, besides lamp renewals. It will therefore be seen that full charges have been debited to the electric light account. It may probably be remarked that no charge has been made on account of wages, but as the engineer in charge of the engines has done this small amount of work as part of his ordinary duty, no charge has been made, for no extra expense has been incurred.

Under these circumstances, the electric light shows a very distinct economy over gas, and it must be acknowledged that, in the case of a weaving shed, the result is very remarkable.

The present is a case where the mill engines have had their surplus power utilised in favour of the electric light installation, a case by no means unusual, and one which would undoubtedly be more frequently adopted if mill-owners were more alive to this fact. In a very large number of instances, the power required for the electric light has been in excess of that which could possibly be obtained from the mill engine, and an independent engine has been provided; and in

other instances it has been considered advisable to have the power for the electric light quite independent. In these circumstances, again, an economy in the use of the electric light has been proved, and in a succeeding number we propose to give some details of the cost of working, with the additional charge of independent engines.

### RESEARCHES ON THE ACTION OF ELECTRICITY UPON CERTAIN GASES.

THE researches of Berthelot into the action of electric discharges upon gaseous bodies have come to be regarded as classical by physicists. His results have been accumulated by a patient investigation which it would well become our younger scientists to emulate. Unfortunately, for the cause of true science, the tendency of the times is, in many matters of great importance, becoming characterised by a certain degree of hurry which, if persisted in, will be fatal to many a career, and, what is worse, to many a question of scientific interest and practical usefulness.

Long ago Berthelot began the systematic study of the action of electricity upon gases and vapours. One of these was carbonic oxide [ $\text{CO}$ ]. This gas has been known for more than a hundred years, having first been obtained by Lavoisier in 1776. Priestly was familiar with it but, by some strange delusion he supposed that it was the gas which we now know as hydrogen. Carbonic oxide can be made in many ways, most of which are strictly chemical in character. Amongst other methods that of Buff and Hofmann (vide *Liebig's Annalen der Chemie*, vol. 113, p. 140) is of interest to electricians. They produced it by passing a series of electric sparks through carbonic acid gas,  $\text{CO}_2$ .

Carbonic oxide when pure is a slightly odorous gas without taste or colour, it will burn and it is extremely poisonous.

There are few compound gases but are influenced by the decomposing action of the electric spark. Carbonic oxide is a typical instance of this; electric sparks, according to Berthelot, cause a partial decomposition to carbonic anhydride ( $\text{CO}_2$ ), and if the  $\text{CO}_2$  be removed by absorption the change proceeds (vide *Annales de Chimie et de Physique*, Series 5, Vol. XXX, p. 547).

Dixon, writing in the *Journal of the Chemical Society*, Vol. XLIX., p. 103, states that sparks from a Leyden jar will decompose carbonic oxide, but that only about half per cent. of the total gas is decomposed by this form of electricity. This scientist has also investigated the action of electricity upon a mixture of carbonic oxide and oxygen. He finds that such a mixture is burnt to carbonic anhydride by the application of an electric spark, just as it is by the application of flame. If, however, both gases are perfectly dry, no chemical change occurs when the spark is passed. A mere trace of steam present is sufficient to render the mixture explosive. If only a very small quantity of steam is present, the change takes place very slowly under the action of electricity; but when the amount of steam is increased, the rapidity of the explosion is increased proportionately. It appears that the steam acts as a carrier of oxygen to the carbonic oxide: it is probably reduced to hydrogen, and this is then oxidised again. Dixon's work may be read in the *Transactions of the Royal Society* for 1884, p. 617. Buff and Hofmann thought that a dry mixture of carbonic oxide and oxygen would not explode, but L. Meyer's experiments seem to prove that such a mixture can be exploded if the operator will use a sufficiently strong spark; the temperature is thus made very high. Other conditions, however, appear to be necessary. The gases must be under considerable pressure: the more dilute the gaseous mixture is, the more difficult it is to explode (vide *Berichte der Deutschen Chemischen Gesellschaft*, Vol. XIX., p. 1,099).

When sparks from an induction coil are passed into a mixture of carbonic oxide and steam, the constituents are dissociated and recombined, the result being carbonic anhydride, a little formic acid, and sometimes free carbon. This observation is also due to Dixon.

It has, further, been shown that if hydrogen and oxygen, the constituents of steam, be added to carbonic oxide, the mixture will explode on the application of an electric spark, and carbonic anhydride and water will be formed. The ratio of these products to each other depends, curiously enough, upon the shape of the vessel, and on the pressure up to a certain limit, which may be called the "critical pressure"; above this limit the ratio is independent of the shape of the vessel. It would be interesting to trace the causes of this very curious result.

Returning now to the researches of Berthelot. In the *Bulletin de la Société Chimique de Paris*, series (2), Vol. XXI., p. 102, is a paper in which he asserts that carbonic oxide is decomposed by the silent electric discharge being converted into carbonic anhydride by a brown substance to which he assigned the formula  $\text{C}_5\text{O}_4$ . Brodie, however, argued at the time that the composition was best expressed by the formula  $\text{C}_4\text{O}_3$ .

Now, according to the more recent researches of P. Schutzenberger, the composition of the dark brown product is variable, and, further, the condensation of the carbonic oxide ceases as soon as the gas contains 10 per cent. of carbonic anhydride.

Schutzenberger's experiments, which have just been described before the French Academy of Science, were made with a simple discharge tube of the Wilde-Berthelot form, the open end dipping under mercury, whilst the armatures were acidified water.

Under these conditions the rate of condensation varied considerably, but was practically constant for the same tube used in the same way. The solid product had the composition:—

Carbon ...	...	...	...	45.6
Hydrogen ...	...	...	...	0.6
Oxygen ...	...	...	...	53.8
				100.0

When the armatures of acidified water were replaced by mercury condensation was much slower, and the black product had the composition:—

Carbon ...	...	...	...	46.4
Hydrogen ...	...	...	...	0.9
Oxygen ...	...	...	...	52.7
				100.0

If the armatures were surrounded by jackets containing dry air, and every precaution taken to exclude moisture, very little condensation took place, even when the discharge was continued for 48 hours. It follows that the presence of small quantities of water is essential to the formation of the black product, and Schutzenberger considers that the electric discharge carries oxygen and water through the glass, and that there is also some evidence of a transport of matter in the opposite direction, since the total quantity of carbon in the condensed product and the carbonic anhydride was less than that in the carbonic oxide which disappeared.

Berthelot, in a still more recent contribution to the proceedings of the same learned body, states that condensation of carbonic oxide under the influence of the silent electric discharge takes place even when the gas is separated from water by the walls of two tubes, and by an intervening air space, the gas and the apparatus having been very carefully dried.

The condensation and the composition of the residual gas show that the solid matter has the composition  $\text{C}_4\text{O}_3$ , which confirms his earlier experiments described in the *Bulletin de la Société Chimique de Paris*, Series 2, Vol. XXI., p. 102, and in the *Annales de Chimie et de Physique*, Series 5, Vol. XVII., p. 142.

Berthelot is also at variance with Schutzenberger with regard to the question of the electric discharge causing the passage of water through the glass. He

considers that there is no scientific evidence of it, and that Schutzenburger is only hazarding an opinion.

Schutzenburger, however, has rejoined that in some experiments described in the *Comptes Rendus*, Vol. CX., p. 681, evidence is there given which fully bears out his views. There is, however, reason to believe that the presence of the moisture is to be accounted for by the extreme difficulty of perfectly drying either glass or mercury.

But there is room for independent effort on other lines of research, for evidently the whole truth concerning the action of the silent electric discharge upon carbonic oxide has not yet been revealed.

Quite recently the condensation of benzene and acetylene, under the influence of the silent discharge, has been placed under investigation by Schutzenburger.

Benzene,  $C_6H_6$ , is a hydrocarbon which has not yet been prepared by electrical methods. In its normal state, at ordinary temperature and pressure, it is a colourless, mobile, strongly refracting liquid, which will burn with a luminous flame. It is usually prepared from coal tar by distillation, fractionation and rectification, according to methods which have been developed by Faraday, Hofmann and Mansfield.

Although it has hitherto been found impossible to prepare benzene by the action of electricity, it is susceptible to change under its influence. If induction sparks be passed through liquid benzene, a gaseous mixture is formed which contains 42 per cent. of acetylene and 57 per cent. of hydrogen. This fact was observed by Destrem (vide *Bulletin de la Société Chimique de Paris*, Series 2, Vol. XLII., p. 267).

Acetylene, on the other hand, can be produced by electricity acting upon the elements carbon and hydrogen, of which it is constituted. Acetylene, called, also, ethine and ethylene, is an ill-smelling gas which occurs normally in coal gas. It is generated by the incomplete combustion of hydrocarbons. Its characteristic odour may be observed when a Bunsen-lamp flame "strikes down" and burns within the chimney.

Berthelot prepared acetylene synthetically by passing hydrogen over charcoal, heated to whiteness, in the electric arc (vide *Comptes Rendus*, Vol. LIV., p. 640).

Dewar obtained the same gas when hydrogen was passed through holes drilled through the centre of carbon points at the same time as these points were discharging powerful sparks (vide *Proceedings of the Royal Society*, Vol. XXIX., 1880).

Acetylene can also be made by another method, devised by Berthelot, which consists in exposing marsh, or coal gas, to the sparks of a powerful induction coil (vide *Comptes Rendus*, LIV., p. 515). The vapours of many organic compounds, e.g., alcohol, ether, acetene, ethylene, benzene, &c., likewise yield acetylene, when induction sparks are passed through them. This was discovered by De Wilde. Berthelot has also obtained it by the electrolysis of a solution of potassium aconitate or succinate. To prepare acetylene in large quantity, however, it would be best to resort to purely chemical methods.

The study of the action of the silent discharge upon acetylene and benzene was conducted by Schutzenberger as follows:

The tubes containing the substances to be experimented upon were hermetically sealed, and thus the contents were cut off from any possible absorption of moisture from the air. It was found that after the discharge had been continued for five or six hours, the inner tube was very liable to break, a result due to the fact that the prolonged action of the discharge makes the glass brittle. If the tubes are quite vacuous fracture takes place after a very few minutes.

Under the influence of the silent discharge, benzene vapour gradually condenses to a pale yellow, resinous, transparent solid, the liquid benzene gradually disappearing. The product contains

Carbon	...	...	85.9 to 91.63	per cent.
Hydrogen	...	...	7.1 "	7.81 " "
Oxygen	...	...	0.7 "	7.0 " "

The composition of the product depends upon whether it is formed on the inner tube or the outer tube.

		C.		H.		O.
Inner tube	...	90.54	...	7.30	...	2.10
Outer "	...	87.14	...	7.48	...	5.38

The results agree with those obtained with acetylene, which gives a product containing 2 to 5 per cent. of oxygen.

Schutzenberger also adduces what he considers further evidences of his theory, that the action of the silent electric discharge affects the glass so that it becomes permeable to water.

It is only by carefully studying the chemical and physical properties of substances that we can form any true conception of the nature of these bodies; possibly the same principle may hold with regard to the various phases of electricity, and hence by studying closely their chemical effects upon well-known bodies as well as their own purely physical characteristics, we may in time arrive at a more lucid conception of these also.

## THE ELECTRO-MAGNET.\*

By Prof. SILVANUS P. THOMPSON, D.Sc., B.A., M.I.E.E.

### LECTURE I.

Historical Introduction—Generalities about Forms and Uses of Electro-magnets—The Magnetic Properties of Iron.

### INTRODUCTORY.

AMONGST the great inventions which have originated in the lecture room in which we are met are two of special interest to electricians—the application of gutta-percha to the purpose of submarine telegraph cables, and the electro-magnet. This latter invention was first publicly described, from the very platform on which I stand, on May 23rd, 1825, by William Sturgeon, whose paper is to be found in the forty-third volume of the "Transactions of the Society of Arts." For this invention we may rightfully claim the very highest place. Electrical engineering, the latest and most vigorous offshoot of applied science, embraces many branches. The dynamo for generating electric currents, the motor for transforming their energy back into work, the arc lamp, the electric bell, the telephone, the recent electro-magnetic machinery for coal mining, for the separation of ore, and many other electro-mechanical contrivances, come within the purview of the electrical engineer. In every one of these, and in many more of the useful applications of electricity, the central organ is an electro-magnet. By means of this simple and familiar contrivance—an iron core surrounded by a copper wire coil—mechanical actions are produced at will, at a distance, under control, by the agency of electric currents. These mechanical actions are known to vary with the mass, form, and quality of the iron core, the quantity and disposition of the copper wire wound upon it, the quantity of the electric current circulating around it, the form, quality, and distance of the iron armature upon which it acts. But the laws which govern the mechanical action in relation to these various matters are by no means well known, and, indeed, several of them have long been a matter of dispute. Gradually, however, that which has been vague and indeterminate becomes clear and precise. The laws of the steady circulation of electric currents, at one time altogether obscure, were cleared up by the discovery of the famous law of Ohm. Their extension to the case of rapidly interrupted currents, such as are used in telegraphic working, was discovered by Helmholtz; whilst to Maxwell is due their further extension to alternating, or, as they are sometimes called, undulatory currents. All this was purely electric work. But the law of the electro-magnet was still undiscovered; the magnetic part of the problem was still buried in obscurity. The only exact reasoning about magnetism dealt with problems of another kind; it was couched in language of a misleading character; for the practical problems connected with the electro-magnet it was worse than useless. The doctrine of two magnetic fluids distributed over the end surfaces of magnets, which under the sanction of the great names of Coulomb, of Poisson, and of Laplace, had unfortunately become recognised as an accepted part of science, along with the law of inverse squares. How greatly the progress of electro-magnetic science has been impeded and retarded by the weight of these great names it is impossible now to gauge. We now know that for all purposes, save only those whose value lies in the domain of abstract mathematics, the doctrine of the two magnetic fluids is false and misleading. We know that magnetism, so far from residing on the end or surface of the magnet, is a pro-

\* Cantor Lecture. Delivered before the Society of Art January 20th, 1890.

perty resident throughout the mass; that the internal not the external magnetisation is the important fact to be considered; that the so-called free magnetism on the surface is, as it were, an accidental phenomenon; that the magnet is really most highly magnetised at those parts where there is least surface magnetisation; finally, that the doctrine of surface distribution of fluids is absolutely incompetent to afford a basis of calculation such as is required by the electrical engineer. He requires rules to enable him not only to predict the lifting power of a given electro-magnet, but also to guide him in designing and constructing electro-magnets of special forms suitable for the various cases that arise in his practice. He wants in one place a strong electro-magnet to hold on to its armature like a limpet to its native rock; in another case he desires a magnet having a very long range of attraction, and wants a rule to guide him to the best design; in another he wants a special form having the most rapid action attainable; in yet another he must sacrifice everything else to attain maximum action with minimum weight. Toward the solution of such practical problems as these the old theory of magnetism offered not the slightest aid. Its array of mathematical symbols was a mockery. It was as though an engineer asking for rules to enable him to design the cylinder and piston of an engine were confronted with receipts how to estimate the cost of painting it.

Gradually, however, new light dawned. It became customary, in spite of the mathematicians, to regard the magnetism of a magnet as something that traverses or circulates round a definite path, flowing more freely through such substances as iron, than through other relatively non-magnetic materials. Analogies between the flow of electricity in an electrically-conducting circuit, and the passage of magnetic lines of force through circuits possessing magnetic conductivity, forced themselves upon the minds of experimenters, and compelled a mode of thought quite other than the previously accepted. So far back as 1821, Cumming\* experimented on magnetic conductivity. The idea of a magnetic circuit was more or less familiar to Ritchie,† Sturgeon,‡ Dove,§ Dub,|| and De La Rive,¶ the last-named of whom explicitly uses the phrase, "a closed magnetic circuit." Joule\*\* found the maximum power of an electro-magnet to be proportional to "the least sectional area of the entire magnetic circuit," and he considered the resistance to induction as proportional to the length of the magnetic circuit. Indeed, there are to be found scattered in Joule's writings on the subject of magnetism, some five or six sentences, which, if collected together, constitute a full statement of the whole matter. Faraday,†† considered that he had proved that each demagnetic line of force constitutes a closed curve; that the path of these closed curves depended on the magnetic conductivity of the masses disposed in proximity; that the lines of magnetic force were strictly analogous to the lines of electric flow in an electric circuit. He spoke of a magnet surrounded by air being like unto a voltaic battery immersed in water or other electrolyte. He even saw the existence of a power, analogous to that of electromotive force in electric circuits, though the name, "magnetomotive force," is of more recent origin. The notion of magnetic conductivity is to be found in Maxwell's great treatise (vol. ii., p. 51), but is only briefly mentioned. Rowland,‡‡ in 1873, expressly adopted the reasoning and language of Faraday's method in the working out of some new results on magnetic permeability, and pointed out that the flow of magnetic lines of force through a bar could be subjected to exact calculation; the elementary law, he says, "is similar to the law of Ohm." According to Rowland, the "magnetising force of helix" was to be divided by the "resistance to the lines of force," a calculation for magnetic circuits which every electrician will recognise as precisely as Ohm's law for electric circuits. He applied the calculations to determine the permeability of certain specimens of iron, steel, and nickel. In 1882,§§ and again in 1883, Mr. R. H. M. Bosanquet||| brought out at greater length a similar argument, employing the extremely apt term, "Magnetomotive Force," to connote the force tending to drive the magnetic lines of induction through the "magnetic resistance," or, as it will be frequently called in these lectures, the magnetic "reluctance" of the circuit. In these papers the calculations are reduced to a system, and deal not only with the specific properties of iron, but with problems arising out of the shape of

the iron. Bosanquet shows how to calculate the several resistances (or reluctances) of the separate parts of the circuit, and then add them together to obtain the total resistance (or reluctance) of the magnetic circuit.

Prior to this, however, the principle of the magnetic circuit had been seized upon by Lord Elphinstone and Mr. Vincent, who proposed to apply it in the construction of the dynamo-electric machines. On two occasions\* they communicated to the Royal Society the results of experiments to show that the same exciting current would evoke a larger amount of magnetism in a given iron structure, if that iron structure formed a closed magnetic circuit, than if it were otherwise disposed.

In recent years the notion of the magnetic circuit has been vigorously taken up by the designers of dynamo machines, who, indeed, base the calculation of their designs upon this all-important principle. Having this, they need no laws of inverse squares of distances, no magnetic moments, none of the elaborate expressions for surface distribution of magnetism, none of the ancient paraphernalia of the last century. The simple law of the magnetic circuit, and a knowledge of the properties of iron, are practically all they need. About four years ago, much was done by Mr. Gisbert Kapp† and by Drs. J. and E. Hopkinson‡ in the application of these considerations to the design of dynamo machines, which previously had been a matter of empirical practice. To this end the formulæ of Prof. Forbes§ for calculating magnetic leakage, and the researches of Profs. Ayrton and Perry|| on magnetic shunts, contributed a not unimportant share. As the result of the advances made at that time, the subject of dynamo design was reduced to an exact science.

It is the aim and object of the present course or lectures to show how the same considerations which have been applied with such great success to the subject of the design of dynamo electric machines may be applied to the study of the electro-magnet. The theory and practice of the design and construction of electro-magnets will thus be placed, once for all, upon a rational basis. Definite rules will be laid down for the guidance of the constructor, directing him as to the proper dimensions and form of iron to be chosen, and as to the proper size and amount of copper wire to be wound upon it in order to produce any desired result.

First, however, a historical account of the invention will be given, followed by a number of general considerations respecting the uses and forms of electro-magnets. These will be followed by a discussion of the magnetic properties of iron and steel and other materials; some account being added of the methods used for determining the magnetic permeability of various brands of iron at different degrees of saturation. Tabular information is given as to the results found by different observers. In connection with the magnetic properties of iron the phenomenon of magnetic hysteresis is also described and discussed. The principle of the magnetic circuit is then discussed with numerical examples, and a number of experimental data respecting the performance of electro-magnets are adduced, in particular those bearing upon the tractive power of electro-magnets. The law of traction between an electro-magnet and its armature is then laid down, followed by the rules for pre-determining the iron cores and copper coils required to give any prescribed tractive force.

Then comes the extension of the calculation of the magnetic circuit to those cases where there is an air gap between the poles of the magnet and the armature; and where, in consequence, there is leakage of the magnetic lines from pole to pole. The rules for calculating the winding of the copper coils are stated, and the limiting relation between the magnetising power of the coil and the heating effect of the current in it is explained. After this comes a detailed discussion of the special varieties of form that must be given to electro-magnets in order to adapt them to special services. Those which are designed for maximum traction, for quickest action, for longest range, for greatest economy when used in continuous daily service, for working in series with constant current, for use in parallel at constant pressure, and those for use with alternate currents, are separately considered.

Lastly, some account is given of the various forms of electro-magnet mechanism which have arisen in connection with the invention of the electro-magnet. The plunger and coil is specially considered as constituting a species of electro-magnet adapted for a long range of motion. Modes of mechanically securing long range for electro-magnets, and of equalising their pull over the range of motion of the armature, are also described. The analogies between sundry electro-mechanical movements, and the corresponding pieces of ordinary mechanism are traced out. The course is concluded by a consideration of the various modes of preventing or minimising the sparks which occur in the circuits in which electro-magnets are used.

#### HISTORICAL SKETCH.

The effect which an electric current, flowing in a wire, can exercise upon a neighbouring compass needle was discovered by

Oersted in 1820.\* This first announcement of the possession of magnetic properties by an electric current was followed speedily by the researches of Ampère,† Arago,‡ Davy,§ and by the devices of several other experimenters, including De la Rives|| floating battery and coil, Schweigger's¶ multiplier, Cumming's\*\* galvanometer, Faraday's†† apparatus for rotation of a permanent magnet, Marsh's‡‡ vibrating pendulum, and Barlow's§§ rotating star-wheel. But it was not until 1825 that the electro-magnet was invented. Davy had, indeed, in 1821, surrounded with temporary coils of wire the steel needles upon which he was experimenting, and had shown that the flow of electricity around the coil could confer magnetic power upon the steel needles. But from this experiment it was a grand step forward to the discovery that a core of soft iron, surrounded by its own appropriate coil of copper, could be made to act not only as a powerful magnet, but as a magnet whose power could be turned on or off at will, could be augmented to any desired degree, and could be set into action and controlled from a practically unlimited distance.

The electro-magnet, in the form which can first claim recognition for these qualities, was devised by William Sturgeon,||| and is described by him in the paper which he contributed to the proceedings of the Society of Arts in 1825, accompanying a set of improved apparatus for electro-magnetic experiments.¶¶ The

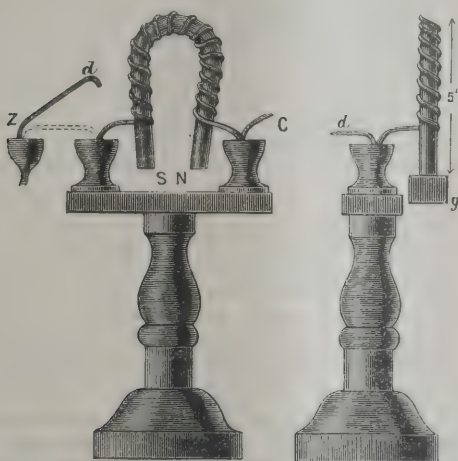

FIG. 1.

FIG. 2.

STURGEON'S FIRST ELECTRO-MAGNET.

Society of Arts rewarded Sturgeon's labours by awarding him the silver medal of the Society and a premium of thirty guineas. Amongst this set of apparatus are two electro-magnets, one of

horseshoe shape (figs. 1 and 2) and one a straight bar (fig. 3). It will be seen that the former figures represent an electro-magnet consisting of a bent iron rod about one foot long and half inch in diameter, varnished over and then coiled with a single left-handed spiral of stout uncovered copper wire of 18 turns. This coil was found appropriate to the particular battery which Sturgeon preferred, namely, a single cell containing a spirally enrolled pair of zinc and copper plates of large area (about 130 square inches) immersed in acid; which cell, having small internal resistance would yield a large quantity of current when connected to a circuit of small resistance. The ends of the copper wire were brought out sideways and bent down so as to dip into two deep connecting cups, marked z and c, fixed upon a wooden stand. These cups, which were of wood, served as supports to hold up the electro-magnet, and, having mercury in them, served also to make good electrical connection. In fig. 2 the magnet is seen sideways, supporting a bar of iron, y. The circuit was completed to the battery through a connecting wire, d, which could be lifted out of the cup, z, so breaking circuit when desired, and allowing the weight to drop. Sturgeon added in his explanatory remarks that the poles, N and S, of the magnet will be reversed if you wrap the copper wire about the rod as a right-handed screw, instead of a left-handed one, or, more simply, by reversing the connections with the battery, by causing the wire that dips into the z cup to dip into the c cup, and vice versa. This electro-magnet was capable of supporting 9 lbs. when thus excited.

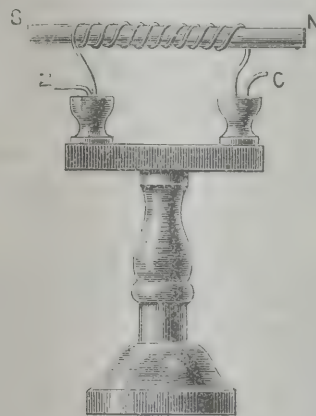

FIG. 3.—STURGEON'S STRAIGHT BAR ELECTRO-MAGNET.

Fig. 3 shows another arrangement to fit on the same stand. This arrangement communicates magnetism to hardened steel bars, as soon as they are put in, and renders soft iron within it magnetic during the time of action; it only differs from figs. 1 and 2 in being straight, and thereby allows the steel or iron bar to slide in and out.

For this piece of apparatus and other adjuncts accompanying it, all of which are described in the Society's "Transactions" for 1825, Sturgeon, as already stated, was awarded the Society's silver medal and a premium of 30 guineas. The apparatus was deposited in the museum of the Society, which therefore might be supposed to be the proud possessor of the first electro-magnet ever constructed. Alas for the vanity of human affairs, the Society's museum of apparatus has long been dispersed, this priceless relic having been either made over to the now defunct Patent Office Museum, or otherwise lost sight of.

Sturgeon's first electro-magnet, the core of which, weighing about 7 oz., was able to sustain a load of 9 lbs., or about 20 times its own weight. At the time it was considered a truly remarkable performance. Its single layer of stout copper wire was well adapted to the battery employed, a single cell of Sturgeon's own particular construction, having a surface of 130 square inches, and therefore of small internal resistance. Subsequently, in the hands of Joule, the same electro-magnet sustained a load of 50 lbs., or about 114 times its own weight. Writing in 1832 about his apparatus of 1825, Sturgeon used the following magniloquent language:—

"When first I showed that the magnetic energies of a galvanic conducting wire are more conspicuously exhibited by exercising them on soft iron than on hard steel, my experiments were limited to small masses—generally to a few inches of rod iron of about half an inch in diameter. Some of those pieces were employed while straight, and others were bent into the form of a horse-shoe magnet, each piece being encompassed by a spiral conductor of copper wire. The magnetic energies developed by those simple arrangements are of a very distinguished and exalted character, as is conspicuously manifested by the suspension of a considerable weight at the poles during the period of excitation by the electric influence.

"An unparalleled transiency of magnetic action is also displayed in soft iron, by an instantaneous transition from a state of total inactivity to that of vigorous polarity, and also by a simultaneous reciprocity of polarity in the extremities of the bar—versatilities in this branch of physics for the display of which soft iron is pre-eminently qualified, and which, by the agency of electricity, become demonstrable with the celerity of thought, and

||| William Sturgeon, the inventor of the electro-magnet, was born at Whittington, in Lancashire, in 1783. Apprenticed as a boy to the trade of a shoemaker, at the age of nineteen he joined the Westmoreland Militia, and two years later enlisted into the Royal Artillery, thus gaining the chance of learning something of science, and having leisure in which to pursue his absorbing passion for chemical and physical experiments. He was forty-two years of age when he made his great, though at the time unrecognised, invention. At the date of his researches in electro-magnetism, he was resident at 8, Artillery Place, Woolwich, at which place he was the associate of Marsh, and was intimate with Barlow, Christie, and Gregory, who interested themselves in his work. In 1835 he presented a paper to the Royal Society, containing descriptions, *inter alia*, of a magneto-electric machine with longitudinally-wound armature, and with a commutator consisting of half-disks of metal. For some reason this paper was not admitted to the "Philosophical Transactions;" he afterwards printed it in full, without alteration, in his volume of Scientific Researches, published by subscription in 1850. From 1836 to 1843 he conducted the "Annals of Electricity." He had now removed to Manchester, where he lectured on electricity at the Royal Victoria Gallery. He died at Prestwich, near Manchester, in 1850. There is a tablet to his memory in the church at Kirkby Lonsdale, from which town the village of Whittington is distant about two miles. A portrait of Sturgeon in oils, and said to be an excellent likeness, is believed still to be in existence; but all inquiries as to its whereabouts have proved unavailing. At the present moment, so far as I am aware, the scientific world is absolutely without a portrait of the inventor of the electro-magnet.

¶¶ "Trans. Society of Arts," 1825, xliii., p. 38.

illustrated by experiments the most splendid in magnetism. It is, moreover, abundantly manifested by ample experiments that galvanic electricity exercises a superlative degree of excitation on the latent magnetism of soft iron, and calls for its recondite powers with astonishing promptitude, to an intensity of action far surpassing anything which can be accomplished by any known application of the most vigorous permanent magnet, or by any other mode of experimenting hitherto discovered. It has been observed, however, by experimenting on different pieces selected from various sources, that, notwithstanding the greatest care be observed in preparing them of a uniform figure and dimensions, there appears a considerable difference in the susceptibility which they individually possess of developing the magnet powers, much of which depends upon the manner of treatment at the forge, as well as upon the natural character of the iron itself.\*

"The superlative intensity of electro-magnets, and the facility and promptitude with which their energies can be brought into play, are qualifications admirably adapted for their introduction into a variety of arrangements in which powerful magnets so essentially operate, and perform a distinguished part in the production of electro-magnet rotations; whilst the versatilities of polarity of which they are susceptible are eminently calculated to give a pleasing diversity in the exhibition of that highly interesting class of phenomena, and lead to the production of others inimitable by any other means."†

Sturgeon's further work during the next three years is best described in his own words:—

"It does not appear that any very extensive experiments were attempted to improve the lifting power of electro-magnets, from the time that my experiments were published in the 'Transactions of the Society of Arts, &c.,' for 1825, till the latter part of 1828. Mr. Watkins, philosophical instrument maker, Charing Cross, had, however, made them of much larger size than any which I had employed, but I am not aware to what extent he pursued the experiment.

"In the year 1828, Prof. Moll, of Utrecht, being on a visit to London, purchased of Mr. Watkins an electro-magnet weighing about 5 lbs.—at that time I believe the largest which had been made. It was of round iron, about one inch in diameter, and furnished with a single copper wire twisted round it eighty-three times. When this magnet was excited by a large galvanic surface, it supported about 75 lbs. Prof. Moll afterwards prepared another electro-magnet, which, when bent, was 12½ inches high, 2½ inches in diameter, and weighed about 26 lbs.; prepared like the former with a single spiral conducting wire. With an acting galvanic surface of 11 square feet, this magnet would support 154 lbs., but would not lift an anvil which weighed 200 lbs.

"The largest electro-magnet which I have yet (1832) exhibited in my lectures weighs about 16 lbs. It is formed of a small bar of soft iron, 1½ inch across each side; the cross piece, which joins the poles, is from the same rod of iron, and about 3½ inches long. Twenty separate strands of copper wire, each strand about 50 feet in length, are coiled round the iron, one above another, from pole to pole, and separated from each other by intervening cases of silk. The first coil is only the thickness of one ply of silk from the iron; the twentieth, or outermost, about half-an-inch from it. By this means the wires are completely insulated from each other without the trouble of covering them with thread or varnish. The ends of wire project about two feet, for the convenience of connection. With one of my small cylindrical batteries, exposing about 150 square inches of total surface, this electro-magnet supports 400 lbs. I have tried it with a larger battery, but its energies do not seem to be so materially exalted as might have been expected by increasing the extent of galvanic surface. Much depends upon a proper acid solution; good nitric or nitrous acid, with about six or eight times its quantity of water, answers very well. With a new battery of the above dimensions and a strong solution of salt and water, at a temperature of 190° Fahr., the electro-magnet supported between 70 and 80 lbs., when the first seventeen coils only were in the circuit. With the three exterior coils alone in the circuit, it would just support the lifter, or cross piece. When the temperature of the solution was between 40° and 50°, the magnetic force excited was comparatively very feeble. With the innermost coil alone, and a strong acid solution, this electro-magnet supports about 100 lbs.; with the four outermost wires, about 250 lbs. It improves in power with every additional coil until about the twelfth, but not perceptibly any further; therefore the remaining eight coils appear to be useless, although the last three, independently of the innermost seventeen, and at the distance of half-an-inch from the iron, produce in it a lifting power of 75 lbs.

"Mr. Marsh has fitted up a bar of iron much larger than mine, with a similar distribution of the conducting wires to that devised

and so successfully employed by Professor Henry. Mr. Marsh's electro-magnet will support about 560 lbs. when excited by a galvanic battery similar to mine. These two, I believe, are the most powerful electro-magnets yet produced in this country.

"A small electro-magnet, which I also employ on the lecture table, and the manner of its suspension is represented by fig. 4. The magnet is of cylindric rod iron, and weighs four ounces; its poles are about a quarter of an inch asunder. It is furnished with six coils of wire in the same manner as the large electro-magnet before described, and will support upwards of 50 lbs.

"I find a triangular gin very convenient for the suspension of the magnet in these experiments. A stage of thin board, supporting two wooden dishes, fastened, at a proper height, to two of the legs of the gin. Mercury is placed in these vessels, and the dependent amalgamated extremities of the conducting wires dip into it—one into each portion.

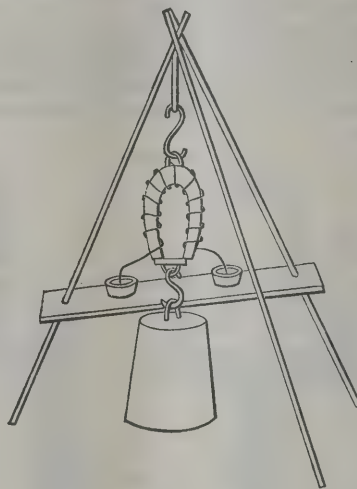

FIG. 4.—STURGEON'S LECTURE-TABLE ELECTRO-MAGNET.

"The vessels are sufficiently wide to admit of considerable motion of the wires in the mercury without interrupting the contact, which is sometimes occasioned by the swinging of the magnet and attached weight. The circuit is completed by other wires, which connect the battery with these two portions of mercury. When the weight is supported as in the figure, if an interruption be made by removing either of the connecting wires, the weight instantaneously drops on the table. The large magnet I suspend in the same way on a larger gin; the weights which it supports are placed one after another on a square board, suspended by means of a cord at each corner from a hook in the cross-piece, which joins the poles of the magnet.

"With a new battery, and a solution of salt and water, at a temperature of 190° Fahr., the small electro-magnet, fig. 3, supports 16 lbs."

In 1840, after Sturgeon had removed to Manchester, where he assumed the management of the "Victoria Gallery of Practical Science," he continued his work, and in the seventh memoir in his series of researches he wrote as follows:—

"The electro-magnet belonging to this Institution is made of a cylindrical bar of soft iron, bent into the form of a horse-shoe magnet, having the two branches parallel to each other, and at the distance of 4½ inches. The diameter of the iron is 2.75 inches, it is 18 inches long when bent. It is surrounded by 14 coils of copper wire, seven on each branch. The wire which constitutes the coils is ⅛th of an inch diameter, and in each coil there are about 70 feet of wire. They are united in the usual way with branch wires, for the purpose of conducting the currents from the battery. The magnet was made by Mr. Nesbit. . . . The greatest weight sustained by the magnet in these experiments is 12½ cwt., or 1,386 lbs., which was accomplished by 16 pairs of plates, in four groups of four pairs in series each. The lifting power by 19 pairs in series was considerably less than by ten pairs in series; and but very little greater than that given by one cell or one pair only. This is somewhat remarkable, and shows how easily we may be led to waste the magnetic powers of batteries by an injudicious arrangement of its elements."\*

At the date of Sturgeon's work the laws governing the flow of electric currents in wires were still obscure. Ohm's epoch-making enunciation of the law of the electric circuit appeared in "Poggendorff's Annalen" in the very year of Sturgeon's discovery, 1825, though his complete book appeared only in 1827, and his work, translated by Dr. Francis into English, only appeared (in Taylor's "Scientific Memoirs," vol. ii.) in 1841. Without the guidance of Ohm's law it was not strange that even the most able experimenters should not understand the relations between battery and circuit which would give them the best effects. These had to be found by the painful method of trial and failure. Pre-eminent amongst those who tried was Prof. Joseph Henry, then of the Albany Institute, in New York, later of Princeton, New Jersey, who succeeded in effecting an important improvement. In 1828,

\* "I have made a number of experiments on small pieces, from the results of which it appears that much hammering is highly detrimental to the development of magnetism in soft iron, whether the exciting cause be galvanic or any other. And although good annealing is always essential, and facilitates to a considerable extent the display of polarity, that process is very far from restoring to the iron that degree of susceptibility which it frequently loses by the operation of the hammer. Cylindric rod iron of small dimensions may very easily be bent into the required form, without any hammering whatever; and I have found that small electro-magnets made in this way display the magnetic powers in a very exalted degree."

† Sturgeon's "Scientific Researches," p. 113.

\* Sturgeon's "Scientific Researches," p. 188.

led on by a study of the "multiplier" (or galvanometer), he proposed to apply to electro-magnetic apparatus the device of winding them with a spiral coil of wire "closely turned on itself," the wire being of copper from  $\frac{1}{16}$ th to  $\frac{1}{8}$ th of an inch in diameter, covered with silk. In 1831 he thus describes\* the results of his experiments:—

"A round piece of iron, about  $\frac{1}{4}$  of an inch in diameter, was bent into the usual form of a horse-shoe, and instead of loosely coiling around it a few feet of wire, as is usually described, it was tightly wound with 35 feet of wire, covered with silk, so as to form about 400 turns; a pair of small galvanic plates, which could be dipped into a tumbler of diluted acid, was soldered to the ends of the wire, and the whole mounted on a stand. With these small plates the horse-shoe became much more powerfully magnetic than another of the same size, and wound in the same manner, by the application of a battery composed of 28 plates of copper and zinc, each eight inches square. Another convenient form of this apparatus was contrived by winding a straight bar of iron, 9 inches long, with 35 feet of wire, and supporting it horizontally on a small cup of copper containing a cylinder of zinc—when this cup, which served the double purpose of a stand and the galvanic element, was filled with dilute acid, the bar became a portable electro-magnet. These articles were exhibited to the institute in March, 1829. The idea afterwards occurred to me that a sufficient quantity of galvanism was furnished by the two small plates, to develop, by means of the coil, a much greater magnetic power in a larger piece of iron. To test this, a cylindrical bar of iron half an inch in diameter, and about 10 inches long, was bent into the shape of a horseshoe, and wound with 30 feet of wire; with a pair of plates containing only  $2\frac{1}{2}$  square inches of zinc, it lifted 15 lbs. avoirdupois. At the same time, a very material improvement in the formation of the coil suggested itself to me on reading a more detailed account of Prof. Schweigger's galvanometer, and which was also tested with complete success upon the same horseshoe. It consisted in using several strands of wire, each covered with silk, instead of one. Agreeably to this construction, a second wire, of the same length as the first, was wound over it, and the ends soldered to the zinc and copper in such a manner that the galvanic current might circulate in the same direction in both, or, in other words, that the two wires might act as one. The effect by this addition was doubled, as the horseshoe, with the same plates before used, now supported 28 lbs.

"With a pair of plates four inches by six inches, it lifted 39 lbs., or more than fifty times its own weight.

"These experiments conclusively proved that a great development of magnetism could be effected by a very small galvanic element, and also that the power of the coil was materially increased by multiplying the number of wires without increasing the number of each."†

Not content with these results, Prof. Henry pushed forward on the line that he had thus struck out. He was keenly desirous to ascertain how large a magnetic force he could produce when using only currents of such a degree of smallness as could be transmitted through the comparatively thin copper wires, such as bell-hangers use. During the year 1830 he made great progress in this direction, as the following extracts show:—

"In order to determine to what extent the coil could be applied in developing magnetism in soft iron, and also to ascertain, if possible, the most proper lengths of the wires to be used, a series of experiments was instituted jointly by Dr. Philip Ten Eyck and myself. For this purpose 1,060 feet (a little more than one-fifth of a mile) of copper wire of the kind called bell wire, .045 of an inch in diameter, were stretched several times across the large room of the Academy.

"Experiment 1.—A galvanic current from a single pair of plates of copper and zinc two inches square was passed through the whole length of the wire, and the effect on a galvanometer noted. From the mean of several observations, the deflection of the needle was  $15^{\circ}$ .

"Experiment 2.—A current from the same plates was passed through half the above length, or 530 feet of wire; the deflection in this instance was  $21^{\circ}$ .

By a reference to a trigonometrical table, it will be seen that the natural tangents of  $15^{\circ}$  and  $21^{\circ}$  are very nearly in the ratio of the square roots of 1 and 2, or of the relative lengths of the wires in these two experiments.

"The length of the wire forming the galvanometer may be neglected, as it was only 8 feet long.

"Experiment 3.—The galvanometer was now removed, and the whole length of the wire attached to the ends of the wire of a small soft iron horse-shoe a quarter of an inch in diameter, and wound with about 8 feet of copper wire with a galvanic current from the plates used in Experiments 1 and 2. The magnetism was scarcely observable in the horseshoe.

"Experiment 4.—The small plates were removed, and a battery composed of a piece of zinc plate 4 inches by 7 inches, surrounded with copper, was substituted. When this was attached immediately to the ends of the 8 feet of wire wound round the horseshoe, the weight lifted was  $4\frac{1}{2}$  lbs.: when the current was passed through the whole length of wire (1,060 feet) it lifted about half an ounce.

"Experiment 5.—The current was passed through half the length of wire (530 feet) with the same battery; it then lifted two ounces.

"Experiment 6.—Two wires of the same length as in the last experiment were used, so as to form two strands from the zinc and copper of the battery; in this case the weight lifted was four ounces.

"Experiment 7.—The whole length of the wire was attached to a small trough on Mr. Cruikshank's plan, containing 25 double plates, and presenting exactly the same extent of zinc surface to the action of the acid, as the battery used in the last experiment. The weight lifted in this case was 8 oz.; when the intervening wire was removed, and the trough attached directly to the ends of the wire surrounding the horseshoe, it lifted only seven ounces.

"It is possible that the different states of the trough, with respect to dryness, may have exerted some influence on this remarkable result; but that the effect of a current from a trough, if not increased, is but slightly diminished in passing through a long wire is certain.

"But, be this as it may, the fact that the magnetic action of a current from a trough is, at least, not sensibly diminished by passing through a long wire is directly applicable to Mr. Barlow's project of forming an electro-magnetic telegraph; and it is also of material consequence in the construction of the galvanic coil. From these experiments it is evident that in forming the coil we may either use one very long wire or several shorter ones, as the circumstances may require; in the first case, our galvanic combinations must consist of a number of plates, so as to give 'projectile force;' in the second it must be formed of a single pair.

"In order to test on a large scale the truth of these preliminary results, a bar of soft iron, 2 inches square and 20 inches long, was bent into the form of a horseshoe,  $9\frac{1}{2}$  inches high; the sharp edges of the bar were first a little rounded by the hammer, it weighed 21 lbs.; a piece of iron from the same bar, weighing 7 lbs., was filed perfectly flat on one surface, for an armature or lifter; the extremities of the legs of the horse-shoe were also truly ground to the surface of the armature; around this horseshoe 540 feet of copper bell-wire were wound in 9 coils of 60 feet each: these coils were not continued around the whole length of the bar, but each strand of wire according to the principle before mentioned, occupied about two inches, and was coiled several

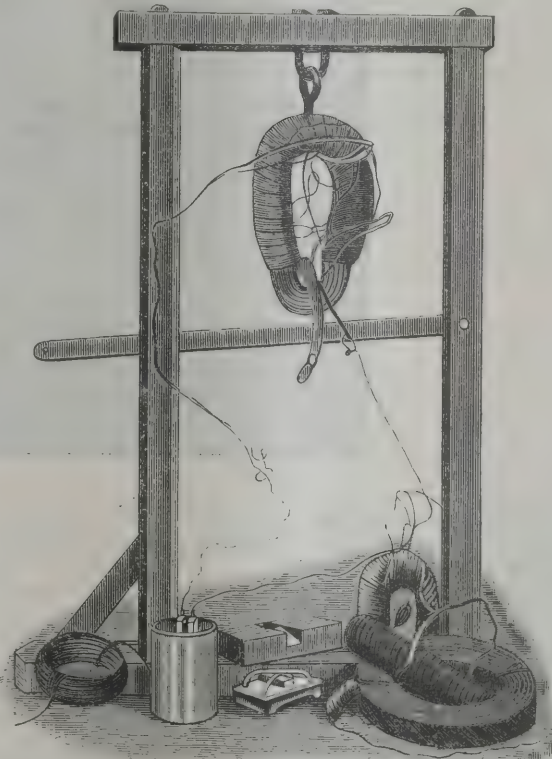

FIG. 5.—HENRY'S ELECTRO-MAGNET.

This figure, copied from the *Scientific American*, December 11th, 1880, represents Henry's electro-magnet, still preserved in Princeton College. The other apparatus at the foot, including a current-reverser, and the ribbon-coil used in the famous experiments on secondary and tertiary currents, were mostly constructed by Henry's own hands.

times backward and forward over itself; the several ends of the wires were left projecting and all numbered, so that the first and last end of each strand might be readily distinguished. In this manner we formed an experimental magnet on a large scale, with which several combinations of wire could be made by merely uniting the different projecting ends. Thus if the second end of the first wire be soldered to the first end of the second wire, and so on through all the series, the whole will form a continued coil of one long wire.

"By soldering different ends the whole may be formed into a double coil of half the length, or into a triple coil of one-third the length, &c. The horseshoe was suspended in a strong

\* Silliman's "American Journal of Science," January, 1831, xix., p. 400.

† "Scientific Writings of Joseph Henry," p. 39.

rectangular wooden frame, three feet nine inches high and twenty inches wide, an iron bar was fixed below the magnet, so as to act as a lever of the second order; the different weights supported were estimated by a sliding weight in the same manner as with a common steel-yard (see sketch). In the experiments immediately following (all weights being avoirdupois) a small single battery was used, consisting of two concentric copper cylinders with zinc between them; the whole amount of zinc surface exposed to the acid from both sides of the zinc was  $\frac{3}{4}$ th of a square foot; the battery required only half a pint of dilute acid for its submersion.

"Experiment 8.—Each wire of the horseshoe was soldered to the battery in succession, one at a time; the magnetism developed by each was just sufficient to support the weight of the armature, weighing 7 lbs.

"Experiment 9.—Two wires, one on each side of the arch of the horseshoe, were attached; the weight lifted was 145 lbs.

"Experiment 10.—With two wires, one from each extremity of the legs, the weight lifted was 200 lbs.

"Experiment 11.—With three wires, one from each extremity of the legs and one from the middle of the arch, the weight supported was 300 lbs.

"Experiment 12.—With four wires, two from each extremity, the weight lifted was 500 lbs. and the armature; when the acid was removed from the zinc, the magnet continued to support for a few minutes 130 lbs.

"Experiment 13.—With six wires the weight supported was 570 lbs.; in all these experiments the wires were soldered to the galvanic element; the convection in no case was formed with mercury.

"Experiment 14.—When all the wires (nine in number) were attached, the maximum weight lifted was 650 lbs., and this astonishing result, it must be remembered, was produced by a battery, containing only  $\frac{3}{4}$ ths of a square foot of zinc surface, and requiring only half a pint of dilute acid for its submersion.

"Experiment 15.—A small battery, formed with a plate of zinc 12 inches long and 6 inches wide, and surrounded by copper, was substituted for the galvanic elements used in the last experiment; the weight lifted in this case was 750 lbs.

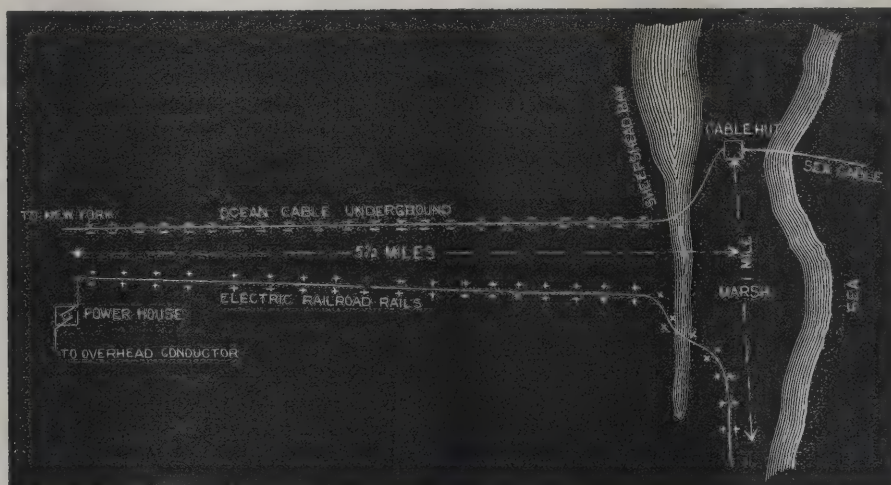

for silk thread, which in these investigations became a very considerable item of expense. He also made a number of experiments with iron bonnet wire, which being found in commerce already wound, might possibly be substituted in place of copper. The result was that with very short wire the effect was nearly the same as with copper, but in coils of long wire with a small galvanic element it was not found to answer. Dr. Beck also constructed a horseshoe of round iron one inch in diameter, with four coils on the plan before described. With one wire it lifted 30 lbs., with two wires 60 lbs., with three wires 85 lbs., and with four wires 112 lbs. While we were engaged in these investigations, the last number of the *Edinburgh Journal of Science* was received containing Professor Moll's paper on 'Electro-Magnetism.' Some of his results are in a degree similar to those here described; his object, however, was different, it being only to induce strong magnetism on soft iron with a powerful galvanic battery. The principal object in these experiments was to produce the greatest magnetic force with the smallest quantity of galvanism. The only effect Prof. Moll's paper has had over these investigations has been to hasten their publication; the principle on which they were instituted was known to us nearly two years since, and at that time exhibited to the Albany Institute.\*

(To be continued.)

## POLARISATION OF THE EARTH BY HEAVY CURRENTS.†

By CHARLES CUTTRISS.

WHILE investigating further the causes of the disturbances experienced when testing the Commercial Cable Company's cable which lands at Coney Island, an account of which will be found in the *Electrical Engineer* of August 6th,‡ certain phenomena have been noticed which may be interesting as showing the effect

"Experiment 16.—In order to ascertain the effect of a very small galvanic element on this large quantity of iron, a pair of plates, exactly one inch square, was attached to all the wires; the weight lifted was 85 lbs.

"The following experiments were made with wires of different lengths on the same horseshoe.

"Experiment 17.—With six wires, each 30 feet long, attached to the galvanic element, the weight lifted was 375 lbs.

"Experiment 18.—The same wires used in last experiment were united so as to form three coils of 60 feet each; the weight supported was 290 lbs. This result agrees nearly with that of experiment 11, though the same individual wires were not used; from this it appears that six short wires are more powerful than three of double the length.

"Experiment 19.—The wires used in Experiment 10, but united so as to form a single coil of 120 feet of wire, lifted 60 lbs.; while in Experiment 10 the weight lifted was 200 lbs.; this is a confirmation of the result in the last experiment.

"In these experiments, a fact was observed which appears somewhat surprising; when the large battery was attached, and the armature touching both poles of the magnet, it was capable of supporting more than 700 lbs., but when only one pole is in contact it did not support more than 5 or 6 lbs., and in this case we never succeeded in making it lift the armature (weighing 7 lbs.). This fact may perhaps be common to all large magnets, but we have never seen the circumstance noticed of so great a difference between a single pole and both.

"A series of experiments was separately instituted by Dr. Ten Eyck, in order to determine the maximum development of magnetism in a small quantity of soft iron.

"Most of the results given in this paper were witnessed by Dr. L. C. Beck, and to this gentleman we are indebted for several suggestions, and particularly that of substituting cotton well waxed

of heavy currents in polarising the ground when it is used as a return circuit for an electric road, and also the great distance at which such effects are felt.

On Sunday, August 17th, an attempt was made from my office in the Drexel Building, New York, to take the usual weekly test of the condition of the cable, but without success, as, owing to the violent and erratic movements of the mirror, it was impossible to get a reliable reading. It was then determined to measure, if possible, the differences of potential that caused such disturbances. In order to make the method of procedure clear, it will be well to state that the underground circuits of the company extend from Wall Street in a northerly direction to the Bronx River, a distance of about 12 miles, and in a southerly direction to Coney Island, also about 12 miles. As there is nothing to my knowledge in the vicinity of the Bronx River terminus to cause any electrical disturbance of the earth's potential, the grounding at that station and at Coney Island of one of their wires gives a very ready way of detecting in New York any variations of potential that may take place at either end.

The first series of experiments were made between

\* Scientific Writings of Joseph Henry, p. 49.

† *Electrical Engineer*, of New York.

‡ See *ELECTRICAL REVIEW* for August 22nd.

the hours of 10.45 a.m. and noon of August 17th, and showed that between Bronx River and New York there was a fairly steady difference of potential of from .8 to 1 volt; but between New York and Coney Island there was a difference of potential varying rapidly from .1 to 3.5 volts, the extreme fluctuations often occurring in four or five seconds. The potential difference between Bronx River and Coney Island was about the same as between New York and Coney Island, or perhaps a trifle higher, and also very unsteady.

It was useless to do anything more until the electric road closed down, so the experiments were abandoned till midnight. At 12.25 a.m. I found a very heavy current between Coney Island and New York, but could not detect the running of any cars. Measurements now showed a positive difference of potential of 4.5 volts; this remained fairly steady till about 1 a.m., when the potential commenced to fall slowly and steadily. At 1.15 a.m. the galvanometer denoted an equal potential at both ends of the line, but the movement of the mirror still continued, slowly crossing the zero and indicating an opposite, or negative, potential wave, which by 1.25 a.m. had reached 3.5 volts negative. It then began to drop, reaching zero at 1.40 a.m., and continued on until it showed a positive difference of .8 volt, where it remained steady, showing that the earth at Coney Island had become normal, as the difference of .8 volt corresponded with the reading between New York and Bronx River. I might state that the New York ground potential was checked off by the Bronx River circuit every five minutes in order to make sure that the variations were not due to local causes.

From the results obtained in the above experiments it is quite evident that there is an actual polarisation of the ground for an unknown distance from the rails of the electric road. The accompanying diagram will make clear the relative positions of the electric road and the ocean cable. The first long, positive (+) current, I think, must be caused by a direct flow of current from the rails through the sea and across the marsh and Sheepshead Bay to the sheathing of the cable; consequently, when the current is cut off from the rails, this direct current gradually drops, and as the current due to the polarisation asserts itself, for an instant the ground at the point of connection between the conductor and sheathing becomes neutral from the action of equal and opposite forces. But, as the negative current from the ground surrounding the cable discharges along the sheathing, that being the path of least resistance, it produces a negative potential at the end of the conductor, which rises to a maximum in a few minutes, and then gradually dies away as the condition of the ground becomes normal. If the normal condition of the ground can thus be raised 4.3 volts by a disturbing force at a distance of  $\frac{1}{2}$  mile, the close proximity of these two systems would certainly render the practical working of the weaker one—the cable—almost an impossibility, even if, as suggested by Mr. T. D. D. Lockwood, a duplicate cable were to be laid, as it is mechanically impracticable to construct two cables in which the dielectric resistance, copper resistance, and capacity shall be identical. Consequently, a variation in either of these respects must make itself manifest when the cores are subjected for a considerable distance to violent and rapid electrical strains.

The great difference in this problem over that of equalising telephone or telegraph circuits rests in the extreme delicacy of the receiving apparatus, and the enormous electrostatic capacity of long lengths of submarine cable.

**New York Subway Work.**—The Board of Electrical Control met on August 22nd, in the Mayor's office, and received a report from the Construction Company, which shows the work of burying the wires is going on satisfactorily. The report states that, in 1889, 56,035 feet of subway and 621,430 feet of ducts were laid. Up to the month of August, 1890, 158,181 feet of trench have been dug, and 774,926 feet of ducts laid.

## NOTES.

**The Bradford Corporation Lighting.**—At the meeting of the council, last week, in reply to a question about the electric lighting work, Alderman Priestman said, with regard to the electricity works, that he had given a statement of the loss accrued to December 31st last, and he hoped to present a statement at the end of the present year. So far, the loss was short of £1,000. The electrical department had never been expected to pay in its earlier stages. An engine was now being laid down which would increase the output without augmenting the working cost, and he expected that in a few months the statement would be very much better than it would be if presented now. If the council would appropriate a sum of, say, £10,000 from the profits of the gas department for the benefit of the electric lighting works, they could be made to pay their way. With regard to the mains and services, which stood at the large sum of £177,000, he believed they had value for every penny of the money. He hoped that ere long the committee would be able to show that the electric lighting department was paying its way; but if not, it would be necessary to raise the price to the consumer. There was no cause to regret the steps taken in respect to this question. He had not the least doubt that if they had not taken the powers of supply themselves, they would have had to spend a great deal more money in keeping other people out. The minutes were then adopted.

**Electric Lighting at Fareham.**—The completion of the electric lighting installation at Fareham was celebrated on Thursday evening by a banquet, which was given by Capt. Ramsay and the directors of the local electric lighting company to the principal residents of the town and neighbourhood. The dining-room at the Red Lion was lighted in honour of the occasion by numerous small incandescent lamps, which hung from the ceiling. The street poles, with regard to which an indictment is pending against the company, have been adorned with paint, and can no longer be said to constitute an eyesore, while the lighting by electricity of the main thoroughfares has given general satisfaction to the inhabitants.

**Portsmouth and the Electric Light.**—No definite steps have yet been taken with regard to the introduction of the electric light into Portsmouth by the Corporation, but the committee recently appointed is engaged in collecting information which will be embodied in its report to the council. In all probability the Corporation will decide to obtain its own provisional order, and afterwards sub-let its rights for a short period to the highest bidder among the rival electric companies who are anxious to make a start in the town, but have hitherto been foiled by the "dog-in-the-manger" policy of the municipality. It is whispered that some time since an effort was made to induce the directors of the Portsmouth Gas Company to take up electricity, but they declined, and now it is too late.

**Church Lighting.**—An installation of the electric light is at present being carried out at the Church and Parochial Hall of St. John's the Divine, Vassall Road, Brixton. About 300 incandescent lamps will be used. The plant consists of a gas engine, a dynamo, and a set of accumulators; a motor is also being put down for blowing the organ of the church electrically.

**Electric Lighting at Barnsley.**—The Barnsley Corporation have adjourned the matter of the electric light to enable the Thomson-Houston Company to send in a complete tender. It is probable that although that of the Westinghouse Company was accepted the contracts may not be signed. Several members of the committee have recently visited various central stations, and are so favourably impressed with the Thomson-Houston system that it seems likely that it will prevail.

**Prague Electric Lighting.**—At the end of last year the electric lighting installations in Prague comprised 8,365 incandescence lamps and 143 arc lights, distributed among various factories, theatres and restaurants. The current was obtained from 47 dynamos of a total capacity of 425 kilowatts. Steam engines and gas engines supplied the motive power, the gas engines being in the proportion of 23 per cent.

**Faraday & Son.**—The firm of Faraday & Son, of Berners Street, was one of the first to devote special attention to the production of decorative fittings suitable for lighting by electricity. Their book of designs has gradually grown in size, and the new edition, now being issued, consists of 62 pages of drawings representing brackets, pendants, electroliers, coronæ, standards, figures, hall lanterns, portable lamps, and billiard lights, the registered designs of which, numbering nearly 100, are the property of the firm.

**Holden & Brooke.**—Messrs. Holden and Brooke, of Manchester, have issued a new catalogue, containing several new specialities and the latest developments in exhaust and live steam injector practice. It also gives a series of self-explanatory drawings of injectors fitted up under various conditions, with such instructions as would enable purchasers abroad to know exactly what to order for their requirements.

**Britannia Company.**—We have received catalogue No. 3 from the Britannia Company, consisting of descriptions, illustrations and prices of engineers' tools and amateurs' lathes. The prices, however, are modified by the notice (which so frequently accompanies trade lists now-a-days) that, in consequence of the continued advance in the cost of raw material and wages, all quotations and discounts are from this date withdrawn.

**W. T. Goolden & Co.**—This firm has issued a useful little pamphlet, entitled "Electricity in Every-day Life," explaining the advantages of electric lighting and the transmission of power by electric motors for pumping, ventilating, hoisting, drilling, and a variety of other operations. The illustrations are all representations of appliances that have been actually constructed and set up, and that have proved perfectly successful under ordinary working conditions.

**Sunbeam Lamp.**—A new price list is issued of the sunbeam lamp, which has been found in practice to be specially adapted for lighting large halls, exhibitions, saloons and decks of ships, and similar places. It is pointed out that, with the same engine and dynamo power, nearly double the light can be obtained from this lamp, as compared with groups of small glow lamps; and, compared with arc lamps in opal globes, the sunbeam gives nearly two-thirds the light, is absolutely steady (never falling momentarily in brightness, as does the arc), requires no attention, and is pleasanter in colour.

**Phosphor-Bronze Company.**—We have been favoured with an early copy of the latest descriptive catalogue and pamphlet issued by the Phosphor-Bronze Company. It is stated in the introduction that the company's cog-wheel brand of alloys of phosphor-bronze have been in extensive use for 20 years. The use of phosphor-bronze wire, and especially of Weiller's patent silicium-bronze wire, for telegraph and telephone purposes, has been attended with the most important results, especially as regards the danger of overhead wires and the cost of renewals. Long telegraph lines, for which iron wire, weighing 400 lbs. per mile, was formerly used, is replaced by bronze wire weighing only 100 lbs. per mile, while for telephone lines bronze wire of 38 lbs. per mile has been used where formerly the wire weighed 240 lbs. per mile. The wire being smooth and light, and offering very little surface to wind and snow, is unaffected by the severest storms, so that its use does away with the danger of falling wires and the inconvenience of interrupted communication.

**Electrical Tramways at Boston.**—The West End Electrical Tramway of Boston, U.S., is the largest system, worked by electricity, in the world. There are about 260 miles of line, with 1,600 cars. Until recently these tramways were worked by horses, but experiments in electric traction, carried out by the Thomson-Houston Company, resulted so satisfactorily that horses were done away with altogether, and electricity substituted in their place. The station is the largest electrical one existing, the boiler-house being 160 feet in length by 80 feet in width, and the dynamo room about twice these dimensions. There will be 13 Corliss engines of 1,750 H.P. each, driving 300 H.P. dynamos. The wires are overhead, and it would surprise those who object to this method on the ground of unsightliness to know how little the wires and poles are noticeable.

**The Schanschieff Electric Light and Power Company, Limited.**—Notice is given, that a general meeting of the members of the above-named company will be held at 32, Poultry, at two o'clock, on 17th October next, for the purpose of having the accounts of the liquidation, showing the manner in which the winding up of the affairs of the company has been conducted, and the property of the company disposed of, laid before the company, and hearing any explanation that may be given with reference thereto; and for the purpose of considering such accounts, and, if the same shall be approved, of passing a resolution approving the same; and also of determining, by extraordinary resolution, the manner in which the books, accounts, and documents of the company, and the liquidation thereof, shall be disposed of.—S. DE LISSA, liquidator.

**Australian Cable.**—It is stated by the Press Association that Lord Knutsford has addressed a letter, dated July 9th, to the Governor of South Australia, setting forth the reasons why Her Majesty's Government have refused to comply with the request of the Australian Governments that the Imperial Exchequer should bear a share of the guarantee and subsidies which are necessary to allow the cable companies to reduce their rates to Australia. The letter states that the Agents-General have very fully explained, and have ably supported, the views of their Governments in this matter. The Imperial Government fully sympathise with the object of the subsidy, and recognise the nature and extent of the sacrifices which the Australian colonies are prepared to make with a view of developing and facilitating telegraphic communication. The readiness with which the colonies accepted, at the risk of considerable loss of revenue, the proposal of the Chancellor of the Exchequer for a reduction of the postal rates affords additional reason for the most favourable consideration of any proposal emanating from their incognate matters.

**American Electric Transit Statistics.**—The Census Bureau of America has issued a bulletin which gives interesting information as to transit facilities of the country. The relation between electricity and other motive powers shows the former to have reached a fairly good figure. The figures run:—

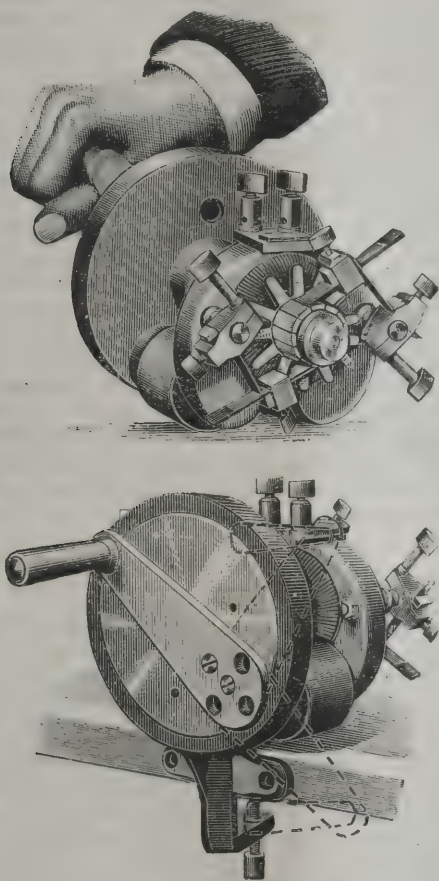

Miles of horse railway ...	...	5,902½
" electric ...	...	1,753
" dummy ...	...	556
" cable ...	...	441
Total mileage...	...	8,652½

Electricity has, therefore, more than 25 per cent. of the total mileage.

**Appointment.**—Mr. Edward A. O'Keeffe, B.E., has been appointed Senior Demonstrator and Lecturer at the City and Guilds of London Technical College, Finsbury, in the place of Mr. W. Robinson, the newly-appointed Professor of Engineering at University College, Nottingham.

**Lectures on Electric Meters.**—A course of six lectures on electric meters, by Prof. Silvanus Thompson, is announced to commence in October at the Finsbury Technical College. This is one of the occasional short courses of lectures which each of the Finsbury professors undertakes annually. The electric lighting arrangements of the college have been lately overhauled and improved. A new Kapp dynamo has replaced the Edison machine formerly employed.

**Austin's "Novel" Hand Dynamo.**—This hand-dynamo has been specially designed for experimental work, either in the laboratory or on the lecture table, for which it is admirably adapted, as from the manner in which it is wound, it will work under all circumstances; no matter whether the external resistance be high or low, the machine will give out a corresponding quantity of current. Great care has been taken in the construction of these machines, so that as much as possible of the manual work expended in turning the

handle is given out at the terminals as electrical energy. As will be seen from the illustrations, the machine is very compact, and has a pleasing appearance. Its output is equal to about six or eight quart Bunsen cells. The machine all complete weighs only 16 lbs. It can be fixed either temporarily or permanently to bench or table. Six different leverages can be got by altering position of handle, three of the most important being shown by dotted lines. There are no belts, cords, or cogwheels used in gearing, which is constructed entirely of metal, working on the principle of rollers and traction—there is consequently very little friction. There are no complicated parts, every part being constructed in the simplest manner possible, and the material and workmanship are of the best.

**The Loan for Electric Lighting at Dublin.**—Mr. Charles P. Cotton, C.E., Board of Trade Inspector, held an inquiry at Dublin last week with reference to an application of the town authorities for a loan of £50,000 for the purpose of an installation for the supply of electricity. The inspector is preparing a report on the evidence.

**Killed by Electricity.**—The *Times* New York correspondent says:—A terrible electric light accident occurred at a theatre here on Monday night. While a lineman was adjusting some wires for illuminating the front of the theatre, he accidentally established a connection, and, receiving the full force of the current, was killed on the spot. The accident caused a most painful impression among a large number of persons who were watching the man's operations.

The *Evening News and Post*, in referring to this matter, says:—"The circumstances will tend strongly to discredit the new system of execution in that State."

"The fact that such torture as this man suffered is possible for a full ten minutes without life being extinguished, shows that electricity is not to be relied upon as a painless method of killing." Surely our evening contemporary does not imagine that the process of electrical execution is to suspend culprits from wires, and let them roast? Moreover, the incidents peculiar to this case had happened previously to Kemmler's fate, so it is rather late in the day to pen comments of this nature.

**The Telephone on the Congo.**—The *Ville de Maranhão*, of the Walford Company of Antwerp, which has just sailed for the Congo, carries all the material necessary for the installation of the first telephone line which is to be placed along the Congo railway. The wires are of phosphor-bronze, and the apparatus is on the Dejongh system, made by Mourlon, of Brussels, with magneto bells of the model adopted, after a competition, by the Administration of Belgian Posts for its private lines, &c.

**Stockholm Electric Lighting.**—The following circular has been sent to members of the Electrical Trade Section of the London Chamber of Commerce by the secretary:—"Having been advised that the notice which appeared in the electrical papers, that the date for the presentation of tenders for the lighting by electricity of the town of Stockholm had been extended from the 15th September to the 12th October, was erroneous, I have, at the request of the chairman of the Electrical Section, and after consultation with the Foreign Office and the Swedish Consul in London, communicated officially with the Stockholm Gas Works. In reply, I have received official telegraphic intimation from that body in language which is considered sufficiently satisfactory, that tenders for the electric lighting contract at Stockholm, *posted from this country not later than the 20th inst., will be considered.*"

**Charterhouse Science and Art Schools and Literary Institute.**—The winter session of this, one of the largest Science and Art Schools in the United Kingdom, and a school which has trained some thousands of teachers for the office of science lecturers, will commence on Saturday, September 27th, 1890, under the presidency of the Rev. Henry Swann, M.A. During the late session about 900 students, mostly elementary teachers, availed themselves of the privileges afforded by this institution, and of this number above 700 presented themselves for examination, and were successful in obtaining a large number of first-class certificates, and also several honors' certificates awarded by the Science and Art Department of South Kensington. Students who were prepared for the Lond. B.Sc. (Inst.) highly distinguished themselves. A National Scholarship of £150 was awarded to one of the female students of the Art school. Instruction of a practical character is given in most of the sciences at a very nominal fee. Students who aim at becoming proficient in chemistry (organic and inorganic) have the opportunity of working in a well-fitted laboratory, capable of accommodating 60 students. Full particulars of the classes may be obtained from C. Smith, organising secretary.

**The Electric Light in Textile Factories.**—In a recent number of *L'Electricien* the arrangement of the electric light in spinning and weaving mills is discussed. For spinning white, unbleached, or clear-coloured yarns in high rooms, the proportion is given of one 12-ampère arc light to 230 square yards, that is 15 by 15 yards. For a 9 or 10-ampère arc the area should not exceed 110 square yards, or  $10\frac{1}{2}$  by  $10\frac{1}{2}$  yards. For weaving, a minimum lighting power of a 12-ampère arc to 133 square yards, or  $11\frac{1}{2}$  by  $11\frac{1}{2}$  yards, is given. For white, unbleached, or clear colours, a 10-ampère arc should be sufficient for an area of 93 square yards, say  $9\frac{1}{2}$  by  $9\frac{1}{2}$  yards; but for black, or dark colours, it is often found necessary to allow only 59 square yards for each 10-ampère arc. In weaving light goods by incandescence lamps, a 10-candle lamp may be used for two looms with unbleached stuff, but when working in coloured yarns two 16-candle lamps are required per loom, and should this be a long one, two 20-candle lamps. These figures appear to be taken from actual experience in Belgium and Germany, but as nearly every factory has a different arrangement of rooms and machinery, the amount of lighting required will not depend so much upon the area of the rooms as upon the method necessary to sufficiently illuminate each particular machine or separate portion of work.

**Elmore's French Patent Copper Depositing Company, Limited.**—This company has been formed to work the process of the Messrs. Elmore in France, with a capital of £200,000 in 100,000 shares of £2 each. 66,750 shares were offered to the public at a premium of 10s. per share. The board of directors includes Sir Richard J. Meade, Major Charles Jones, E. J. Carson, Wm. Elmore, Charles Glendinning Philips, and Sir James D. Mackenzie, Bart. The patents were to be sold to this company by Elmore's Foreign and Colonial Patent Copper Depositing Company for £83,500 cash, £66,500 in shares, and the premiums on the shares (assuming the shares were all taken up), amounting to £33,275, the vendors thus benefiting to the extent of £183,275. The working capital will be £50,000.

**Fraud by a Telegraphist.**—Herbert Wadsworth, assistant postmaster at Milnsbridge, was fined £2 and costs by the West Riding magistrates at Huddersfield on Monday, in each of two cases for wilfully and without due authority altering telegrams with intent to defraud Her Majesty's Postmaster-General. In consequence of complaints as to alterations of telegrams going from this office, a clerk from London was sent on August 28th to make inquiries. This gentleman handed in two telegrams at the Gobar office addressed to different people in Bradford, and containing 58 words. Upon these 2s. 5d. was paid. Defendant condensed messages, and by sending them as duplicates only, placed 1s.  $3\frac{1}{2}$ d. upon them in stamps, pocketing the difference.

**The American Association for the Advancement of Science.**—Professor Nipher is credited with having described a new method of measuring the electrical resistance of liquids before this Society (see page 339). We would like to ask wherein this differs from that devised years ago by Wheatstone, whose apparatus also reversed the galvanometer at the same time? This so-called new method appears to be periodically revived, as we have previously pointed out.

**Blasting by Means of Electricity.**—The work of blowing up the masses of rock which form the dangerous rapids known as the Iron Gates, on the Danube, was commenced on Monday near Greben, M. Baross, the Hungarian Minister of Commerce, firing the first charge by means of electricity.

**The Telegraph in the Chin-Lushai Expedition.**—His Excellency the Governor-General of India, in Council, is glad to acknowledge, through a general order dated September 8th, 1890, the services of Mr. E. O. Walker, Assistant-Superintendent of Telegraphs, and his department, and of Mr. G. Barton Groves, Deputy Inspector of Post Offices, and the Postal Department.

A despatch of the Adjutant-General in India, dated July 16th, states:—The Telegraph Department worked extremely well throughout the expedition.

Lieut.-General B. L. Gordon, C.B., commanding the Burnia district, in a despatch to the Adjutant-General, Madras, dated May 28th, says:—The Telegraph Department has worked well, under many difficulties of transport labour and sickness. The construction of the line kept pace with the advance of the troops into Haka. The wire has been invaluable throughout the operations.

In a despatch dated 31st May, addressed to the Adjutant-General, Brigadier-General V. W. Tregear, commanding the Chillagong column, states:—The whole of the field work has proved laborious and exhausting to all concerned, owing to steep ascents and declivities, and the dense forest and undergrowth, or bamboo jungle, everywhere met with. The whole of the work has, notwithstanding these difficulties, been carried out in a most excellent manner, and reflects the greatest credit on Mr. Walker and all his subordinates. Owing to ill-health, Mr. Walker had to return to India on the 7th March from Fort Tregear, after which date the laying of the line was carried on by Messrs. Rector and Davies, both of whom have worked very hard and well throughout the expedition; the services of the latter officer I had the pleasure of bringing to notice in my final report on last year's expedition. The construction of the line from Fort Lungleh towards Haka was commenced simultaneously with the road, and by the 23rd March had been completed to the Upper Kolodyne, a distance of 65 miles, when orders were received to discontinue the laying of the line towards Haka till next winter, when it can be carried out in a permanent manner.

**A Novel Telephonic Reaction.**—The New York *Electrical Engineer* says:—"We have recently had our attention called to an interesting phenomenon in connection with the telephone, which might be looked upon with suspicion by the uninitiated. While Messrs. Hibbard and Pickernell were conversing recently over one of the lines of the Long Distance Telephone Company, the former, in order to shut out some conversation, placed the receiver with the diaphragm end over the mouthpiece of the long-distance transmitter. The receivers at both ends at once began to give out at musical sound, which continued until the receiver was withdrawn from the mouthpiece of the transmitter. Investigation proved that the effect was due to an action quite similar to that employed in the well-known buzzer, or vibrating bell. An original impulse imparted to the transmitter is conveyed electrically through the primary and secondary circuits to the receiver, which in turn throws it back upon the transmitter through the intervening air, thus constituting a complete electric and acoustic cycle. This battledore and shuttlecock action between receiver and transmitter is continuous as long as the receiver is held against the transmitter, and gives rise to a musical note of high pitch and great uniformity. Of course, it requires a powerful transmitter to produce the phenomenon, the ordinary Blake instrument being incapable of demonstrating it. The effect produced is decidedly novel, and the experiment is well worthy of repetition." We may remark that the experiment is not novel, a precisely similar one having been made several years ago by Mr. Ströh, in the early days of the telephone and microphone; the microphone used was of small dimensions, and was mounted on a diaphragm of gold-beater's skin.

**Personal.**—We understand that Mr. Albright sails tomorrow in the *Servia* with the members of the Iron and Steel Institute, who are about to visit America.

### NEW COMPANIES REGISTERED.

**Elmore's French Patent Copper Depositing Company, Limited.**—Capital £200,000 in £2 shares. Objects: To adopt an agreement between Elmore's Foreign and Colonial Patent Copper Depositing Company, Limited, of the first part, Woodhouse & Rawson United, Limited, of the second part, and this Company of the third part. To carry on in France, and elsewhere, the business of manufacturers of and dealers in copper and other metals, all metallic alloys or compounds of the same, and all goods or articles made of copper or other metals and alloys. To carry on business as electricians, electrical contractors, electrical and mechanical engineers, and suppliers of electricity for the purposes of light, heat, sound, power or otherwise, and of manufacturers of and dealers in all apparatus and things required for the generation, distribution, supply, accumulation and employment of electricity. Signatories (with one share each), A. L. Brockman, 8, The Avenue, Brondesbury; T. E. Marsh, 42, Reighton Road, Upper Clapton; J. North (engineer), 88, Queen Victoria Street; S. Rentall, 121, Vassall Road, Brixton; J. Mumford, 50A, Trinity Square, Borough; J. Moore, 46, Norroy Road, Putney; F. Dewar Summers, 31, Berwick Street, S.W. The signatories are to appoint the first directors. Qualification: 200 shares, or £500 stock. Until otherwise determined by the company in general meeting, the remuneration of the board is to be £200 per annum for each director, with an additional £200 per annum for the chairman, and £100 for the vice-chairman, together with 2½ per cent. commission upon the net profits from manufacturing and upon the revenue accruing from licensing or sub-licensing the Company's patents, and 1 per cent upon net profits from sale of patents, such commission to be divided as the directors think fit. Registered 10th inst. by Wm. Brown, 18, St. Swithin's Lane, secretary.

**Service and Company, Limited.**—Capital £6,000, in £5 shares. Objects: To acquire the business of wholesale and retail ironmonger, carried on at 4, The Octagon, Plymouth; to carry on (if thought wise) the business of an electric light company in all branches, and to supply electricity for light, heat, motive power, or otherwise; and to manufacture and deal in electrical apparatus generally. Signatories (with 1 share each): W. H. Luke, F. S. Willies, A. Yeo, A. N. Cole, T. B. Percy, all of Plymouth; J. Snawdon, Pennycomequick; R. W. C. Barker, Stonehouse. The remuneration of the directors is to be determined by the company in general meeting. Qualification: £125 in shares. Registered 10th inst. by Sir Joseph Causton and Sons, 9, Eastcheap, as agents for Bond and Pearce, Solicitors, 16, Princess Square, Plymouth.

### OFFICIAL RETURNS OF ELECTRICAL COMPANIES.

**Electric Installation and Maintenance Company, Limited.**—An agreement of 25th ult., filed 12th inst., cites that the Electric Construction Corporation, Limited, has carried out an electric installation at Nos. 19 and 20, Walbrook, and is supplying electricity to various customers in the neighbourhood. This company agrees to purchase the said installation and the plant, materials, &c. in connection therewith, for £2,390, payable as to £950 in 6 per cent. debentures and the balance by the allotment to the vendor company of 144 fully paid £10 shares in this company.

**Syndicate of Electrical Engineers, Limited.**—The statutory return of this company, made up to the 7th February, was filed on the 8th ult. The nominal capital is £10,000, divided into 1,900 ordinary and 100 founders' shares of £5 each. 607 shares have been taken up, and the full amount has been called thereupon. The calls paid amount to £600, and unpaid to £7. Registered office, 15, St. Helen's Place.

**Earthy Metals Company, Limited.**—The registered office of this company is at No. 1, Westbourne Terrace, Willesden Green.

**Mulholland, Maugham & Company, Limited.**—The registered office of this company is situate at West Cornforth, R.S.O., Ferryhill, Durham.

**Edison Photographic Toy and Automaton Company, Limited.**—The registered office of this company is at 2, Metal Exchange Buildings, Gracechurch Street.

### CITY NOTES.

#### The Electric and General Investment Company.

THE first ordinary general meeting of this company was held on Tuesday afternoon last, at the offices, Nos. 1 and 2, Great Winchester Street, Old Broad Street, under the presidency of Mr. John Herring.

Mr. J. Cecil Bull (the secretary) read the notice convening the meeting, which stated that it was merely a statutory meeting held in accordance with the requirements of the Companies' Acts, and that there would be no business transacted.

The Chairman remarked that although it was only a formal statutory meeting, it was usual for something to be said on such occasions, either as to the business actually done by the companies or their prospects. He was able to state that the directors had had brought under their notice a considerable number of schemes, some of which looked good, whilst others the board had dismissed as not worthy of their consideration. Two or three of the schemes presented a more than ordinarily favourable outlook. If any one of those schemes turned out successful for the company, it must, with its limited capital, prove of very great advantage to the shareholders. Up to the present, the company had not done any actual business, for they were in a quiescent position. The directors had been very economical in every respect, and had so dealt with the capital as to keep down the expenses in every way possible. In fact, he believed he might with confidence state, that that was one of the cheapest companies ever formed, and the expenses had been confined to a very small outlay, and the capital had been lent out upon good and approved securities in order to bring in interest, so that it should not be lying idle. Therefore, if they took away the amount of the preliminary expenses for the formation of the company, the interest which they were earning on the money paid their expenses, so that their capital was left intact. There was a great deal of business in front of them which might, or might not turn out to be for the benefit of the company. At any rate, the directors had very great hopes. The chairman concluded by giving some particulars as to the arrangements for office and other expenses with the view of keeping down the expenditure as much as possible.

Mr. E. Garckie (director) also corroborated the chairman as to the number of schemes which had been submitted for the consideration of the directors and added, that, of course, the future of the company depended almost entirely upon the development of the electric industries.

**The Woodhouse and Rawson Electric Contract and Maintenance Company, Limited.**—Creditors of the company are required, on or before the 11th day of October, 1890, to send their names and addresses, and the particulars of their debts or claims, and the names and addresses of their solicitors (if any), to Gustavus Adolphus Steinthal, of No. 41, Piccadilly, Bradford, in the county of York, the liquidator of the said company, or in default thereof they will be excluded from the benefit of any distribution made before such claims are received.

**The Direct Spanish Telegraph Company, Limited.**—The board has decided to recommend the payment of the dividend at the rate of 10 per cent. on the preference shares, and a dividend at the rate of 6 per cent. (free of income tax) upon the ordinary shares for half-year ended 30th June last.

### TRAFFIC RECEIPTS.

The Western and Brazilian Telegraph Company, Limited. The receipts for the week ending September 12th, after deducting the fifth of the gross receipts payable to the London Platino-Brazilian Telegraph Company, Limited, were £3,698.

## SHARE LIST OF ELECTRICAL COMPANIES.

Present Amount Issued.	Name.	Stock or Share.	Closing Quotation. (September 11.)	Closing Quotation. (September 18.)	Business done during week ending September 18, 1890.

## WINE AND ELECTRICITY.

[FROM A CORRESPONDENT.]

IN an article of your issue for August 29th, headed "Electricity is Life," you spoke of its use for the improvement of spirituous liquors. This well-meant proposal has formed the subject of careful discussions in Hungary, rich as it is in wines, and it has even culminated in tangible proposals, though of very doubtful value.

Baron von —, a writer on economical subjects, discussed this question at some length in a leader in the *Pester Lloyd*, a journal of a very wide circulation. He wrote:—"One of the most recent advances in the utilisation of electric energy is that of the electrolysis, or decomposition of liquids by means of the electric current. We can scarcely err if in this direction we entertain very bold expectations, and assume that new tracks of unexpected importance for practical life will be opened in this direction. Without doubt, agriculture and its connected arts will derive essential advantages from such inventions and discoveries. The electrolytic purification of sewage seems, as far as it can be ascertained, to be a matter of certainty, and justifies the most sanguine expectations. The question of the general de-fuselising of spirits by means of electrolysis is on the very point of solution, and the same is probably the case with the improvement of wine by the introduction of an electric current."

After a brief historical survey of the recent scientific investigations in this field, the writer of the article continues:—"For this new and promising process we are indebted to the American, Fraser. He takes a different method from that adopted by earlier experimentalists. Whilst they all conducted the current directly into the wine, and thus doubtless produced an effect which might be considered as too much of a good thing, Fraser only allows the electricity to act indirectly. He procured casks about 3 metres in length and  $\frac{1}{4}$ th metre in diameter, and were thus more like a wide pipe than a common cask. He covered the casks with coils of wire, just like the wrappings of an electro-magnet, and passed a strong electric current without interruption through the wires for 10 days. The casks were filled, some with different sorts of wine and others with freshly-distilled raw spirit. At the expiry of the 10 days, the casks had such a strong electric charge that, on touching them, strong electric shocks were experienced! The wine had deposited all its albumenoid matter and had assumed the colour and the bouquet of a fully-matured, ripened product, so as to be already in a merchantable condition. This electrified wine was further distinguished by its great permanence, as if it had been submitted to the Pasteur process. As for the brandy, it had likewise been advantageously modified by the electric treatment, and had acquired the flavour and the aroma of an old spirit many years in cask."

"In presence of such striking results, companies have been already formed in California for introducing the Fraser process on a large scale. It cannot be denied that the above experimental results may be of the greatest practical importance, both for producers of and dealers in wines and spirits. It is unnecessary for us to call the attention of our readers to the enormous pecuniary results which would accrue were it in the power of every dealer to transform his wines within a few days from a crude product to one fully matured and fit for bottling, and to give fresh brandy the flavour of an old product, rich in bouquet."

"Any one who feels an interest in this important question can make the experiment himself without much trouble or outlay. He needs merely to take a few tall, slender casks and to wrap them round with a well insulated copper wire, in such a manner that between every two turns there is left a free interval of 2 to 3 centimetres in width. A constant current is then passed through the wire for the requisite time, either from

a secondary battery or from a dynamo. It is quite practicable to pass the current over from one cask to another, so that a single source of electricity will suffice for a number of casks."

If the reputation of the author did not guarantee the uprightness of his intentions, we might be tempted to view this article as a companion piece to the former farce of the electric sugar refinery. It is really inexplicable that chemical action can be produced by simply circulating a continuous current around a cask of wine! The writer, who is led to his project by the sincerest desire to relieve the wine industry of Hungary, hard pressed by the phylloxera has either not carefully read the descriptions of his authorities or has misunderstood them. In relating how the electric current is passed from cask to cask, forming, in a manner, central stations for refining wines, he forgets to say whether the casks are to be arranged in series or parallel. For persons who might be induced to try the experiment recommended in a paper of such eminence, it is fortunate that the electricity will in this manner have as little effect as the high tension currents have upon the phylloxera. I speak here merely of the experiments for the electric execution of this criminal which have been actually carried out, but have proved total failures. In like manner, the experiments in the *Pester Lloyd*, if useless, will do no harm.

ELECTRICITY AT THE AMERICAN  
ASSOCIATION.\*

By Prof. H. S. CARHART.

THE address of Prof. Cleveland Abbe, vice-president of the Physics section of the American Association for the Advancement of Science, at the recent Indianapolis meeting, was on Terrestrial Physics. It touched upon the obscure question of the origin of terrestrial magnetism. Prof. Abbe concludes from the low permeability of iron at high temperatures that the metallic portions of the earth interior cannot be magnetised, and that terrestrial magnetisation must be restricted to the earth's shell or crust. He therefore inclines to the theory of magnetism derived from terrestrial currents in planes at right angles to the axis of rotation. He reasons that the earth is immersed in a dielectric, and is placed in some kind of electrical field due to solar radiation. If this were the case it would require no inconsiderable currents round the globe as a solenoid to produce the known terrestrial magnetism, since the cause operating to prevent permanent magnetism in the earth's interior would also prevent such material from serving as the core of an electro-magnet.

In the physical section Prof. Mendenhall presented facts, derived from the magnetic observations of the Coast and Geodetic Survey, going to show that magnetographs often record earthquake disturbances, not as mechanical shocks, but as magnetic perturbations. These he conceives to be due to the sudden stresses to which the earth is subjected in earthquakes; and these stresses modify the earth's magnetism. In support of this view he showed, from an analysis of the photographic records of magnetographs, that two diurnal fluctuations in declination depend upon lunar action; and he ascribes these to the stresses in the earth's crust produced by the same forces which raise the tides. The subject will be pursued further by observers of the Geodetic Survey.

Prof. Nipher, of St. Louis, described a new method of measuring the electrical resistance of liquids, such as the internal resistance of a battery. It consists briefly in placing the resistance to be measured in one arm of a bridge with a two-part commutator to effect rapid reversals of the current through the electrolyte. From measurements thus far made the results are found to agree with those of approved methods to within 1 per cent.

Mr. E. G. Merritt described the peculiar behaviour of a galvanometer when used with a thermopile. It consists in small periodic pauses in the deflection of the needle when the thermopile is exposed to a steady source of heat radiation.

These pauses, which may even amount to reversals in the motion of the needle, for a short distance, are always equi-distant in time; and the first maximum bears a definite ratio to the total deflection which the needle will reach if the radiation upon the face of the pile be continued indefinitely. Comparisons of different sources of radiant heat may, therefore, be made by observations of the first maxima occurring at the first pauses of the needle. The phenomenon was shown to be due to the composition of a damped vibration of the needle, and a deflection produced by an E.M.F., the law of variation of which may be expressed by an exponential curve. The paper was an admirable example of a short investigation completely worked out.

\* Electrical Engineer, of New York.

Sections A, B, C, and D of the Association spent one day by invitation at Terre Haute, and held sessions in the Rose Polytechnic Institute. An elegant dinner was served at the Terre Haute House to the 200 guests, and Colonel R. W. Thompson, ex-Secretary of the Navy, made the address of welcome. Colonel Thompson welcomed the Association to the same place 19 years ago. He excited lively interest by his vivid narrative of experience with Morse, and of his efforts to secure a \$25,000 appropriation from Congress to construct an experimental telegraph line. In this connection he said that one of his colleagues was subsequently defeated for Congress because his constituents disapproved of his vote for the appropriation for the telegraph. What a commentary on the righteous judgment of the people!

Many members took occasion during the meeting to ride on the electric railway in Indianapolis. It works admirably; and the central line of iron poles, carrying the wires, is an ornament to the street rather than a disfigurement. A large party accepted the kind invitation of the Parry Manufacturing Company to visit their factory for the purpose of witnessing electric welding on a commercial scale. They saw a single workman welding wagon tires at the rate of about three per minute. Two men were engaged in welding inch axles also, and both operations were conducted with the most gratifying success. The process is very satisfactory to the manufacturers, and its rapid introduction into large plants is assured.

The papers presented to the physics sections of the Association included a relatively smaller number on electrical topics this year than for several meetings. Other departments of physics received a larger share of attention than usual. The papers were of a high average, but none reached the highest water mark.

## ELECTRICAL CENSUS TAKING.

THE chiefs of the Population Division of the United States Census Office celebrated the completion of the count of the population of the United States by a dinner at "Glen Echo" recently. The "Hollerith electric tabulating system" has been in use by the Census Office for the tabulation of the schedules of the population taken under the eleventh census. Superintendent Porter in expressing his congratulations upon the rapid and accurate completion of this great work, spoke as follows:—

It may not have occurred to any of this little band of faithful workers, consisting of chiefs and section chiefs from the Population Division of the Census, that you are celebrating a great event here in this picturesque spot. For the first time in the history of the world the count of the population of a great nation has been made by the aid of electricity. The number of names on every one of 15,000,000 schedules has been registered twice by the nimble and expert fingers of the counters, and the 64,000,000 people have marched, as it were, under the vision of the young men and women who have done such remarkable work with such extraordinary rapidity and precision. What a procession you have had pass before you. The men who wrote those names have had to find them in every human habitation, and existing under every imaginable condition within this vast domain of ours. In June these blanks were distributed throughout the country. In July and August they find themselves back in the Census Office, counted twice and ready for the next statistical treatment. Allowing for the time spent in teaching and in fitting up the machines, the count proper was not commenced before July 1st, and the night force was not organised until some time afterwards. We have actually counted 128,090,000 in six weeks, or the entire population of 64,000,000 twice in that period. Beginning with 2,000 and 3,000 families, or 10,000 and 15,000 persons per day, the operatives progressed in dexterity, until last Thursday no less than 43 counted over 10,000 families or 50,000 persons each, one young lady reaching the astonishing total of 16,071 families or about 80,000 persons. On that day not only the highest averages were reached, but the greatest number counted, the report showing 1,342,318 families or 6,711,590 persons. This represents an average of 8,135 families or 40,675 persons per clerk. In this connection I think it my duty to say that in the "general average" the male clerks, man like, I hear some of the young women whisper, seek refuge behind the petticoats of the gentler sex. The average number counted by the women clerks was 9,590 families, or 47,950 persons, and by men clerks, 6,587 families or 32,935 persons. Thus it will be seen that the women average nearly one-half more than the men. It is also worth noting that of the 43 who counted more than 10,000, 38 were women and only five men. These facts, and indeed the record of the entire six weeks, show that women are better adapted for this particular work than men. They are more exact in touch, more expeditious in handling the schedules, more at home in adjusting the delicate mechanism of the machine, and apparently more ambitious to make a good record.

While I congratulate you on the completion of the rough count, and thank you sincerely for the great interest you have taken in this work, for the many extra hours you have freely given to keep it moving, I must sympathise with you in the sorrowful fact that you have no more countries to count. Alexander is said to have wept because he had no more worlds to conquer, and Hunt and Sutherland in the midst of this gay festivity look solemn and sad at the paltry total of 128,000,000, and, with a ghastly smile, I can

hear them say: "We had to count the population twice in order to reach those figures." Distance is overcome and lessened when we can flash our thoughts thousands of miles in a few minutes, and cross the Atlantic in five days. So it is in census work. With the force that left work this afternoon, working night and day as we have worked, we could, with these electrical machines, count the entire population of the United States in ten days of seven working hours each.

Estimating the population of the civilised world at 650,000,000, we could count it in 100 days; while the bright young women and sturdy young men of our population division could run through the entire population of the earth, which, including Asiatics and savages, is estimated at 1,300,000,000, in less than 200 days, providing places could be found to store the schedules. And while we thus glorify our own little achievement, we must not forget that we have here with us the modest man who invented the wonderful machine with which we have accomplished such magical results.

## BRITISH ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.—LEEDS, 1890.

### RECENT DETERMINATIONS OF THE ABSOLUTE RESISTANCE OF MERCURY.

By R. T. GLAZE BROOK, F.R.S.

(Printed from Notes used for the discussion on Electrical Units in Section A of the British Association, Leeds, September 10th, 1890.)

WE are here to-day to discuss some of the determinations of the value of the ohm when expressed as the resistance of a column of mercury, with a view to seeing if any action is practicable by which the standards in general use may be brought nearer to their theoretical value than they are at present. The time is opportune, for we have the advantage of having in Leeds Prof. Mascart, of Paris, and Prof. Rowland, of Baltimore, under whose directions some of the most important of the investigations we are to consider to-day have been made, and Prof. Barker, one of the American representatives at the Paris Congress. Moreover, it seems probable that a Congress will again meet shortly to consider this question, and a preliminary discussion here may be of value in clearing the ground.

The question at issue is whether the results of experiment are sufficiently in accord with each other to render it probable that any number adopted by us would be generally accepted, and, if so, to determine what that number is.

The problem has two sides. The resistance of a wire is expressed by means of one series of experiments in terms of a length and a time, while by another series of experiments it is expressed in terms of the resistance of mercury, and thus the resistance of mercury is found absolutely. Frequently, however, there is an intermediate step; the resistance of the wire is expressed in terms of some standard resistance, and this standard is expressed in terms of mercury.

The methods employed to compare a standard resistance with that of mercury are all very similar in their nature, and the experiment is not one of very great difficulty. Accordingly we find that the results of the experiments are fairly concordant.

In Table I, column 5 gives the values found in B.A. units for the resistance of a column of mercury 1 metre long, 1 square mm. in section at 0° C.—a Siemens unit, as it is called. The values found by Lord Rayleigh and M. Mascart are higher than later ones. A comparison of the values found for the B.A.U. in ohms and for the Siemens unit in B.A.U. by M. Mascart, leads to the conclusion that possibly his B.A.U. had changed a little between the time at which it was compared with the standards at Cambridge and the time at which it was used. As to Lord Rayleigh's value, the fact that the coil *R* was his principal standard, and the coil *r* has certainly changed relatively to the other coils in the last two years, may help to explain the difficulty, but it must be remembered that *R* had the same value relatively to the others in 1888 as it had in 1881, when examined by Dr. Fleming.

The other numbers are in close accord, except one result of Salvioni's, which must, I think, be capable of a simple explanation. Strecker, Kohlrausch, and Salvioni differ somewhat from Wilkes and myself; in consequence, I believe, of the fact that they worked at the temperature of the room, while Wilkes and I worked at the temperature of melting ice. A small change in the temperature coefficient used by them would easily account for the difference.

Wuilleumeier's mercury coils were the same as those employed by Mascart, Benoit, and de Nerville. We may thus take '9535 B.A.U. as being very accurately the resistance of a column of mercury 100 cm. long 1 square mm. in section.

But when we inquire what are the results which have been obtained for the value, in ohms, of the B.A.U., or of the mercury unit, the discrepancies are considerable.

Let us consider the methods. An admirable summary of these will be found in Wiedemann's *Electricität*, vol. iv., p. 910, or in Mascart and Joubert's *Leçons sur l'Électricité*, ii., pp. 581, *et seq.* They have also been critically discussed by Wiedemann and by Lord Rayleigh in the *Phil. Mag.*, vol. xiv., 1882. We will take them in order,

VALUE OF OHM EXPRESSED AS THE RESISTANCE OF A COLUMN OF MERCURY.

	Observer.	Date.	Method.	Value of B.A.U. in ohms.	Value of 100 centimetres of mercury in B.A.U.	Value of ohm in centimetres of mercury.

I.—Kirchoff's Method.

This has been used by H. F. Weber, Rowland, Mascart, and Glazebrook. The formula may be written—

$$R = \frac{4 \pi M}{T} \cdot h \cdot \frac{\alpha}{\beta}$$

Where M is the coefficient of induction between the coils, T the time of swing of the galvanometer needle,  $\alpha$  the deflection due to primary current,  $\beta$  the throw due to the induced current, and  $h$  a ratio either of two galvanometer constants or of two resistances; all small corrections are omitted.

The main difficulty is in calculating the value of M, which depends approximately on  $a^2/b$  if  $a$  is the radius of either coil, and  $b$  the distance between the coils.

In the coils used by myself the value of  $a$  was about 26 cm.; that of  $b$  varied from 12 to 24 cm. An error of 1 mm. in  $b$  produces an error in the result between 1 in 1,500 and 1 in 2,000. In one position of the coils, the correction arising from the fact that the cross-section of the channel was of finite area was less than 1 in 1,000. There should, it seems to me, be no difficulty in finding M to the one or two in 10,000. The coils used by Rowland and Weber in their earlier experiments, and by Mascart, were smaller. In his last experiment in 1883 Weber used coils of 32 cm. radius. In their later experiments Rowland and Kimball had large coils, about 50 cm. in radius.

The various results are :

H. F. Weber .....	105.37
Rowland .....	106.29
Mascart .....	106.33
Glazebrook .....	106.29

It will be noticed that all H. F. Weber's results are very low. He used as his standard wire a 10-Siemens unit taken from a resistance-box, not a coil which had been compared directly with mercury, and it seems possible that a common error in this affects all his results; he also used large magnets. The other values are in fair agreement, though we may probably agree with Lord Rayleigh in thinking that the limit of accuracy of the method has not been reached.

II.—Weber's Method.

The approximate formula again is

$$R = \frac{2 \pi G g}{T \beta} = \frac{4 \pi^3 N N'}{T \beta} \cdot \frac{a^2}{A}$$

where G is the constant of the galvanometer,  $g$  the area of the earth inductor, and in the second expression,  $a$  is the radius of the inductor, A, of the galvanometer, N and N' being the number of turns on either.

This method was followed by Mascart, who used with a coil of 15 cm. diameter and a galvanometer the constant for which was compared with one of known constant—viz., the inductor. The time taken to turn the inductor was one-fifth of the time of vibration of the galvanometer needle. There is the difficulty of making the axis vertical and the effect of the time of duration of the current on the throw of the galvanometer to consider. My experiments

show that if the effect of the induction current be prolonged for a period of one second, the time of swing being 23 seconds, then the deflections are reduced by 1 per cent. With the circuit open for two seconds the effects are marked.

The same method has been used by G. Wiedemann, who is inclined to think it the best. He employed coils of W. Weber and Zollner, one metre in diameter, which were wound and measured twice. He calculated G using as galvanometer coil a counter-part of the inductor; the effect of the current was determined by measuring effects of a series of impulses at proper moments. The time of turning the inductor was two seconds, while the period of the needle was one minute. This would tend to reduce  $\beta$ , this to increase R, and hence to decrease the length of the column, which was found by comparison with a Siemens unit; the same unit was compared with mercury.

Mascart thinks the difficulties of this method inspire with doubt the results thus obtained. Experiments near the magnetic equator would, Lord Rayleigh points out, decrease the effect of level error. Wiedemann thinks this method is to be recommended for final determinations. Rowland criticises the method.

The results obtained are :

Mascart .....	106.37
Wiedemann .....	106.19

III.—Method of British Association Committee.

$$R = \pi^2 N^2 a \cot. \phi$$

The only measurement, apart from corrections, is that of mean radius. The corrections, however, are important, for the self-induction of the rotating coil requires to be known, while the magnetic field in which the coil is moving is modified by the presence of the magnet at its centre, so that the magnetic moment of this magnet has to be determined. In order to reduce the amount of this correction, this magnetic moment is made small, and this again leads to difficulties.

The following difficulties are urged by Wiedemann :

- (1) Correction due to self-induction. (2) Difficulty of levelling. (3) Want of steadiness from draughts, etc. (4) Small magnetic moment.

In reply, we may say that

- (1) Can be corrected for. (2) Level error common to several methods (see II. above). (3) Effect can be eliminated by experiments with open circuit. (4) Theory of the correction is very simple; a knowledge of M H only is required.

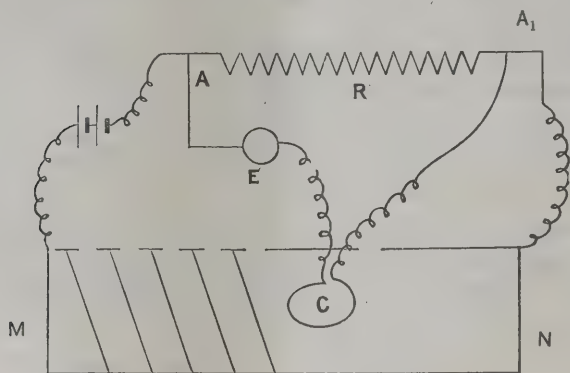

The method was used by Lord Rayleigh, leading to the result, 106.24. It was also employed by H. F. Weber, who used rotation about a horizontal diameter in the magnetic meridian to avoid the correction depending on M/H.

IV.—Foster and Lippmann.

$$R = 2 \pi^2 \frac{a^2}{A} \cot. \phi N N'$$

A rotating coil is used, but contact is made only at the moment when E.M.F. is a maximum, and E.M.F. is balanced by that due to an

external current through a known resistance. Observations have been recently carried out by Wuilleumeier by this method with modifications. He used the induction from a long spiral, MN (see figure), 2 metres long 30 cm. diameter, placed east and west, wound with one layer of wire 2 mm. in diameter. A coil, C, wound on a disc of hard wood, 20 cm. in diameter, rotates in this, and the circuit is closed when the E.M.F. in this a maximum; the E.M.F. thus produced is balanced against that produced in the current in the spiral when flowing through a resistance, R, the action of the earth's magnetism being compensated. One point, A, of R, is in connection with the coil through E, the other end is straight, and a movable contact is established at A<sub>1</sub>, A etc. Corrections for its ends are obtained by shifting the spiral coil. The resistance of R was about 3 ohm, made from a strip of German silver of rectangular section 34.72 metres long, 1 cm. broad, .3 cm. thick, immersed in naphtha.

The primary current was 12 amperes. A Lippmann electrometer was used. The E.M.F. was nearly four volts. The diameter of the rotating bobbin was 20 cm. Hence, error of .1 mm. in mean radius makes error of 1 in 1,000. The formula assumes spiral to be uniformly wound. Result is 106.267.

#### V. Method of damping.

Set a magnet in a coil. The motion of the magnet sets up currents, which react on the magnet and damp it. A relation can be found between these currents, and the rate of damping. To a first approximation it is

$$R = \frac{\pi}{2} \frac{1}{T} G^2 \frac{M}{H} \frac{(\pi^2 + \lambda^2)}{\lambda - \lambda_0}$$

$\lambda, \lambda_0$  being logarithmic decrements.

G has to be compared with the constant of another coil, because of the size of the coil. Let  $h$  be the ratio—

$$R = \frac{2\pi^2}{T} \frac{N^2 h^2}{A^2} \frac{\pi^2 + \lambda^2}{\lambda - \lambda_0} r^3 \tan \alpha.$$

Where A is the radius of standard coil, N the number of its turns,  $\alpha$  the deflection which the magnet produces in Gauss's first position when at a distance,  $r$ .

Further corrections are required for length of magnet, and for the uncertainty as to the distribution of its magnetism and for self-induction.

In the opinion of Lord Rayleigh and Rowland, the final formula is enough to show that the method cannot compete with the others. Other difficulties are that calculation assumes the arc of oscillation is small, G is not independent of the displacement.

Currents are set up in the magnet, which affect its motion. A correction is required for temporary induced magnetisation due to action of current, this may be appreciable. In general there are difficulties in applying the theory.

The method was used by H. F. Weber. His magnet was 8 cm. long, his coil 16 cm. in radius; G was calculated, a uniform distribution of magnetism being assumed.

Dorn introduced corrections to the theory; he found G by comparison with a large coil, compared result with a Siemens unit, verified by Strecker; his magnet was 17 cm. long, closely surrounded by the coil. Wild suspended the magnet bifilarly; it was 29 cm. long, and the coil closely surrounded it; a resistance-box was used.

Kohlrausch's magnet was 20 cm. long, with brass ends. The coil was close to it, G was compared with that of a large galvanometer. Resistance compared directly with a tube calibrated by Strecker.

The results are:

H. F. Weber .....	104.77
Dorn .....	106.24
Wild .....	106.03
Kohlrausch .....	106.32

#### VI.—Lorenz Method.

$$R = n M.$$

The main difficulty lies in the calculation of M. This is more easy than in I, for the disc can readily be measured.

In Lord Rayleigh's apparatus an error in the radius of the coil does not greatly affect result. Further increase of size possible and desirable. The smallness of the effect, and therefore of R is not fatal. See Lord Rayleigh's observations.

Thermo-electric effects can be compensated for.

Results:

Rayleigh .....	106.24
Rowland .....	106.29
Lorenz .....	106.19

Lorenz value is too low because of the size, of the mercury tubes used by him.

#### VII.—Roiti and Himstedt.

$$R = n M \frac{a}{\beta} = n 4 \pi^2 a^2 \frac{N N_1}{1} \frac{a}{\beta}.$$

There is a difficulty in having many contacts, for if the contact does not last all the time supposed,  $\beta$  would be too small, R too large, and the length of column too short. There is also an important correction for the ends, and the assumption is made that the coils are uniformly wound. Another difficulty is the theory of the galvanometer under such discharges.

The resistances were compared with a Siemens unit, and in the case of Roiti with one of Strecker's coils.

The results are:

Roiti .....	105.89
Himstedt .....	105.98

#### VIII.—Calometric Methods.

The results by these methods cannot claim any great accuracy.

Having thus completed the review of the methods, we must look at the results; and after what I have said, we may, I think, reject all work previous to 1882.

The results of H. F. Weber are manifestly too low, while serious doubts attach to the methods of Roiti and Himstedt. For Weber's first method, the early results of W. Weber and Zollner may be omitted compared with those of G. Wiedemann, while the results given by the method of damping will be sufficiently represented by the work of F. Kohlrausch, who alone of those who used this method compared his results with the resistance of mercury directly.

The experiments of Lorenz will not, I think, stand rigid criticism, while, unless I am much mistaken, Lenz, who also used Lorenz' method, has only published results and not details.

We are thus left with the following list, including the results only of those who have made both the mercury and the absolute determinations:—

Lord Rayleigh .....	106.23
Mascart .....	106.33
G. Wiedemann .....	106.19
Rowland .....	106.32
Kohlrausch .....	106.32
Glazebrook .....	106.29
Wuilleumeier .....	106.27

Mean ..... 106.28

If we take in Lord Rayleigh's results for the value of the B.A.U. in ohms, for 100 cm. of mercury in B.A.U. the value .9535 instead of .9541 given by his own experiments, we get, instead of the values 106.21 and 106.24 the values 106.27 and 106.30. The mean, then, of the whole would be 106.29. If we include the three numbers (9, 10, 11) of the table, we get the value 106.30.

It seems, then, to me, that the number 106.30 certainly expresses the true value within one or two in 10,000, and that the time has come for carrying the conclusions of the Paris Congress one place further.

The establishment of the new standardising laboratory calls for some authoritative expression of opinion here in England. Are we prepared to express our opinion?

In 1886, the Standards Committee agreed, on the motion of Sir W. Thomson, (1) to recommend for adoption for a term of ten years the legal ohm of the Paris Congress as a legalised standard sufficiently near to the absolute ohm for commercial purposes, and (2) that at the end of ten years, the legal ohm should be defined to a closer approximation to the absolute ohm.

The Government took no action on this matter, and the opportunity is afforded us of revising, not in ten years, but in four, our provisional suggestion. Shall we replace the 106 cm. by 106.30 cm.

For my part I should be guided greatly by the amount of acceptance that such a decision would meet with. If Prof. Rowland and Prof. Barker, who was with us in 1886, can tell us that they would agree in recommending the Government of the United States to adopt the same view, and if Prof. Mascart thinks that such a course would meet with the approval of himself and his distinguished colleagues in France, I should be heartily glad of it.

If, on the other hand, they press for further time in order that experiments of a higher degree of accuracy, which can no doubt be attained, though probably at great cost, may be carried out, I should deprecate the Committee coming to any conclusion which might pledge them to a number which does not meet with general acceptance.

#### DISCUSSION.

Prof. ROWLAND (America) said, as one of the members of the United States commission for the determination of the ohm, the matter in America was entrusted to me. The commission consisted of Profs. Barker, Trowbridge, and myself. The experiments were carried on at the John Hopkins University, under my superintendence, with considerable appropriation from the United States Government. The experiments have been going on for many years, and we have continued to experiment down to the present time, and, indeed, the whole matter has been gone over by one of my associates, Dr. Duncan, Professor of Applied Electricity

and he, with his students, has determined not only the absolute unit, but also has made a complete determination of the mercury unit. Unfortunately, I cannot bring figures, as I have been travelling for several months, but they have been gone into, as I said, very carefully, and, if I recollect rightly, the number, 106.32, has been slightly diminished. Mr. Glazebrook's criticism, however, has been so exhaustive that I can add very little with respect to it. As to which are the best methods, there are very few who will dispute that the method of Lorenz is the best for this determination. You have a very definite quantity to measure—the diameter of a revolving disc, which is a very definite quantity—and then, as Lord Rayleigh has shown, the determination can be made, so as to almost entirely eliminate the radius effects of the coil, that is the most important feature of the experiment, because nothing is undetermined in the experiment, such as the radius of the coil of wire. You wind the coil in the groove, but as to where the different wires are in the groove it is impossible to determine with any very great accuracy; so, if we can eliminate this quantity, we can get more accurate results. Therefore, all experiments which depend on the square of this quantity, as, for instance, when you have revolving coil, I think all have this source of error. I think the Commission of the United States would be perfectly willing to recommend the figures, so far determined. Those who were connected with the commission will recollect that the United States never recommended to the Government any figures whatever. The 106 decided on by the Paris Conference was never accepted by the United States, even provisionally, and therefore the matter has been left entirely open to the present time, because we felt that you in England would come to some figures of this sort. We are now prepared in America to recommend some figure based on the result here given, and I may mention that the Superintendent of the Coast Survey has intimated to the committee that they are willing to establish a bureau of electrical measurement, under the charge of the United States Coast Survey. I do not suppose they will take up many units, but at least they will take up the unit of resistance, if they have the sanction of the United States Government.

LORD RAYLEIGH said that it made him feel very antiquated to see his name at the head of the list of 18 determinations of the ohm. He thought Mr. Glazebrook was quite right to begin where he did, because before 1882 the results obtained were comparatively wide. At that time discrepancies of 3 per cent. existed. It was very satisfactory to find that now the whole question was narrowed to one in a thousand instead of three in a hundred. Certainly, looking at those figures, and listening to Mr. Glazebrook's able exposition of the methods followed by various observers, it looked very much as if the number obtained by himself for the specific resistance of mercury were a little in error. That number, .9541, was higher than those found by recent experiments. The only difficulty he found in accepting that view was that he found the observation exceedingly easy to make, and probably, for that reason, he was wrong. But still, he was not content with an agreement between the first two or three measurements. The experiments were protracted for a considerable time, and considerable variation was used in preparing tubes, and the degrees of concordance in the results was very great. Certainly, at the time, he would have thought it extremely unlikely that any repetition could have altered the figures .9541 into .9535, or whatever was thought most probable. At the same time, anybody who had had any experience of that kind of work must know that unexpected errors did creep in. Since the publication of Mr. Glazebrook's paper upon the subject, in which to a great extent the same method, and even the same apparatus, was used as that which he (Lord Rayleigh) employed, he had gone into the matter very carefully, in the hope of, perhaps, finding where the difference lay between them. But he had been unable to find any error in the work which led him to the higher number. The notes of the experiments were nearly complete; and it was as easy to make the calculations now as at the time of the experiments. He could not explain the discrepancy, unless there had been a shifting in the standard coils themselves, in comparison with which the mercury tubes were observed. Mr. Glazebrook had shown that if they discarded that number (.9541) and substituted for it the recent comparisons of mercury with the B.A. unit, then the absolute numbers that he (Lord Rayleigh) obtained for one B.A. unit would lead to very nearly the same results for the length of the mercury column as had been obtained by others. It looked as if the general balance of evidence was in favour of 106.30, which Mr. Glazebrook had taken, although he might be sanguine in supposing that we are confident of it to two parts in 10,000. He was in commenting upon Lorenz's work, to say that he had not taken not quite sure whether he had rightly understood Mr. Glazebrook, account of the manner in which a current would enter a wide column of mercury from a wire. It was a good many years since he had taken this into account. He had a distinct impression of functions which would represent the manner of divergence. At any rate, he must have been quite on his guard in that matter. He (Lord Rayleigh) was sometimes inclined to think that a little too much importance was attached to the expression of the resistance of mercury absolutely. Supposing that they could be quite sure the length of the column of mercury was 106.30, what use were they to make of the fact? An electrician, in his laboratory, did not find it easy to set up a mercury tube, and to obtain results by that method. In a factory, it would be still more unlikely that mercury would be employed for the purpose. Practically, to make use of the determination, they must have a wire. He was inclined to think the numbers expressing the B.A. unit were quite

as important as those into which mercury entered. Mr. Glazebrook had explained that a wire was first expressed in absolute measure, and then the comparison was made with mercury. It was very important, no doubt, to make that comparison for standard wires, but it was really the wire that was wanted for practical purposes, and therefore he thought as much importance should be attached to the fifth column of figures as to the last. The only other thing that occurred to him to say was that he did not quite understand why so very much less importance is attached to the determination of the ampère as to the determination of the ohm. They had there a long series of determinations on the subject of the ohm. So far as he knew the received ampère depended upon only two sets of observations, those of Prof. Kohlrausch and himself. It was true that it was more difficult to define the ampère than the ohm, but it was as important that it should be defined; and he would suggest to those who still felt inclined to experiment on the subject of electrical units, to repeat the measurement of the ampère, feeling that that is perhaps liable to greater uncertainty than attached to the ohm.

Prof. BARKER (America), expressed great gratification at the reception they had met with. He had been struck with the clearness and justness of the statements of Mr. Glazebrook in regard to the matter. It had been placed before them in such a manner that the thanks of the section were due to him. He felt that they in America occupied an anomalous position in regard to the ohm. When the Congress of 1881 determined to submit to experimental determination in the various countries, the work was undertaken on behalf of the United States by their committee under the presidency of Prof. Rowland. The work occupied some time, and was made with a great deal of care, in consequence it was not completed when the meeting of 1884 took place. They (the committee) petitioned for a further postponement, in order to enable the results of the American experiments to be presented at the Paris Congress. This, however, was not done. As they all knew, action was taken in Paris upon results which did not include the American observations. Having no part in it, therefore, they should be considered to be entirely independent as to whether 106, which is dignified by the name of the legal ohm, although it has never been legalised in England or America, should be still further legalised by England or the United States, or whether what seemed positive knowledge now should not be legalised. As Mr. Glazebrook said, it was fortunate that the English Government took no action in regard to the matter. He (the speaker) attended the meetings of the committee, and he supposed the pressure of having some legalised standard led to the suggestion of Sir William Thomson that 106 should be adopted. At that time probably that figure came up to their knowledge, but now was an opportune time to take legal action. He seconded Prof. Rowland's opinion that the United States would be very glad to adopt 106.3, which the committee of the B.A. recommended for adoption as the ohm. It would be also great satisfaction if Prof. Mascart would secure similar simultaneous action in France in the same direction. They in America were very much indebted to Englishmen for the work accomplished here, more especially to the various committees of the B.A. He might be allowed to refer to another matter, scarcely germane to the subject under discussion. It would be remembered that at the Paris Exhibition of 1881 the name of Weber was taken away from unit of current, and the name of Ampère substituted, and the name of Coulomb for quantity. At that time, he (the speaker) suggested that the Americans were entitled to some sort of representation, and he suggested the name of Franklin for one of the units, which was seconded by Prof. Mascart. This, however, was not done, and he wished to say that they would support England in the matter of the units, if it would support them in getting in the name of Franklin somewhere.

SIR WILLIAM THOMSON said he was afraid he might be held to be a partisan of 106. He begged to say that he was not, and never was. He thought Mr. Preece would bear him out in that. They fought hard for 106.25 at the Paris Congress, but the case turned out for 106 or nothing; and for the whole German scientists and instrument makers to be left to the Siemens unit. The two brothers Siemens, Werner and William, were present, and they very much desired that a mercury unit should be kept, recommending and suggesting very good reasons for keeping it, reasons to which Lord Rayleigh alluded, and which they still considered of great importance. The mercury unit then was adopted, and the question was how many centimetres, instead of the Siemens 100, was to be taken for the new unit. Now, it so happened that there were no observers present (and there were a considerable number of distinguished men present from Germany and Italy), but no observers whose results went above 106; the average of all the results before the Congress came to almost exactly 106. He urged that Lord Rayleigh's were worth all the others put together, and he believed that he persuaded the mass of the Congress to that fact, but he could not bring them to the point of voting. When four years ago he proposed the ten years period, and that was carried by the B.A., electricians did not live so fast as they did now, and he was only too glad to see that four years had done the work of ten, and he cordially agreed with Mr. Glazebrook, Prof. Barker, and Prof. Rowland in feeling very thankful indeed that the British Government did not take any action on the resolution of the B.A. committee adopted four years ago. He cordially agreed in the idea held now by persons present and many who were absent that now had come the time for fixing the standard at 106.3. He thought that nearer than 106.4. The results were certainly much more than 106.2, and less than 106.4. 106.3 was the nearest whole

number, it was much better than 106. It was within 1 or 2 parts in 10,000 of the true value. One word about the B.A. method. He did not know that there would be any proposal to go on with any more elaborate methods, but if any more great experiments were to be made, he would just say a word for the B.A. method that they had not yet seen all that it could do. He spoke of that very question with Clerk-Maxwell, about levelling and sensibility, and it was obvious that the right place to do the experiment was the equator, and Clerk-Maxwell was ready to go there to do it; and he (Sir William Thomson) believed that if he had been spared he would have kept that in view. Going to the equator would at once increase the sensibility in the ratio of the horizontal force at the equator to the horizontal force in England. It would absolutely do away with all trouble in respect of level. He hoped, if any more observations were made, the B.A. method would be kept in view with that fact, that results at the equator would be more accurate than it was possible to get with observations made in Leeds or at Cambridge, where they had been made. He called attention to the remarkable agreement now between the results of several observations obtained with such very different methods. It was quite surprising to find all come so close to that 106.3, when they considered the great difference between the methods.

Mr. PREECE said he thought to a certain extent he must accept the responsibility of having advised Her Majesty's Government to decline to accept the 106 as the legal unit in 1886, and the reasons for that course were very powerful and very numerous. Any change that would have then been made would have meant most serious expenditure. The number of apparatus adjusted to the B.A. unit, not only in this country but in the colonies and all over the world, was so enormous that any change made would have been a matter involving one costing many thousand pounds, and one that would certainly result in another change within ten years. There is no doubt it would have been wrong then; on the other hand, there is equally no doubt that at the present time we shall be perfectly right in making a change. After hearing what has been said on the subject, he would not have the slightest hesitation in recommending 106.3 to the Institution with which he was connected as representing the true ohm. They must remember that although it might not be absolutely accurate, it was as accurate as most measuring instruments, in some cases far superior. In reply to Lord Rayleigh's question why we did not measure the ampère, the measurement depended not only on the accuracy of the ohm, but also on an accurate knowledge of the measurement of the volt, and when they had the volt represented as accurately as the ohm, then, perhaps, they might fall back upon the ampère. At the moment, the only measurement of the unit, E.M.F., was the measurement made by Lord Rayleigh himself, and he did not think that as accurate as the mean results brought before them that day. Although the discussion before them took in view general electrical units, he did not wish to raise any question except on that of the ohm, still he wanted gentlemen present and electricians to take into consideration at some future day the entire alteration of the volt. It was a most unfortunate thing that the volt was taken as equivalent to  $10^8$  C.G.S. units. It had been done so because the particular volt and the E.M.F. of the Daniell cell were very closely allied. But if the volt had been made  $10^9$  instead of  $10^8$ , then their practical unit of current the ampère, would have been exactly the same as the unit C.G.S. that is now nearly always used in enquiries, so he felt quite sure that the day was not far distant when all electricians would have to take into consideration the enlargement of the volt, and it would be beneficial in enlarging the other units at the same time. To take an instance, there was the watt, this was too small to use; as the unit of the power they had to call it the kilowatt, and because it was called that it did not go down so smartly as if it had been called the watt. If they raised the volt to  $10^9$  they would also raise the watt, then the watt would become very nearly a man power and  $\frac{1}{2}$  of horse power, and they would obtain a unit of power scientifically accurate, and so closely allied to existing units used by engineers in general that the ridiculous horsepower would be driven out of existence, and the watt used instead. With regard to Professor Barker's suggestion as to the name of Franklin, they all agreed that if it was possible to slip in the name they would, but it was not the only name they wanted to slip in, there was Henry which had been suggested in America as the unit of self-induction, he could promise Mr. Barker that if any new nomenclature was wanted the names of Franklin and Henry should receive consideration.

The following discussion took place on Messrs. Lawrence and Harries's paper "On Alternating Currents in relation to the Human Body," and Mr. Wilson Hartnell's paper on "Fire Insurance Rules," published last week.

Mr. PREECE said the two papers read touched upon a question which was at the present time of great importance, that is, the danger to person. The way in which Messrs. Lawrence and Harries had worked at the question from a personal point of view was a right one. They had attacked the question in a scientific manner, very gradually accumulating well assorted facts, and very gradually giving them to understand how the human frame became influenced by the currents, and the result to a certain extent was startling; it was startling to find that alternating

currents were so much more painful than continuous currents, and also startling to find that these sensations of discomfort could be produced with such ridiculously little currents. Those who had spent their lives, as he had, in the practical applications of electricity, knew something about the effects of shocks. He supposed, in his career, he must have received a million shocks, or perhaps more; at any rate, when those two gentlemen read their paper before the Institution of Electrical Engineers, he was conscious of the fact that the severe shocks they had experienced were due to such ridiculously low currents. Small as the currents were, they possessed a danger; not that the currents themselves would hurt, but that the reception of a shock would frighten a timid person and probably cause him or her to fall down, and produce, as is often the case, a stoppage of the heart and death from other causes. The subject of the danger of currents was brought up last year at the meeting at Newcastle, and it led to considerable discussion. In the address, he ventured at that time to point out how extremely unscientific and inaccurate any attempt to introduce electricity for executionary purposes was until they knew about its influence, and the result had fully confirmed his doubts of the whole matter, and they had seen that they scarcely knew what they were going to do; and from the papers before them, they had a great deal more to learn before they dared to use electricity for the purpose of execution. There were many points he would commend to the notice of Messrs. Lawrence and Harries before they had thoroughly thrashed out the matter, one in particular was the effect of electrostatic charges on the human frame, and also the effect of self-induction of electro-magnetic apparatus, through the sudden rise and fall of the current. Continuous currents rose very gradually, and did not influence much the human frame, but if a current rose suddenly, they would be certain to get severe and serious shocks. Complimenting the readers on their paper, he did not think the effect of such papers would be to increase the timidity of the public in the use of electricity, because after they had shown the currents were dangerous, it was equally easy to see that they could be absolutely safe, and while an alternating current of 100 volts, with a frequency of 60 or 70, might hurt them very much, there was no reason why they should receive a shock. The dangers could be made simply innocuous by placing the wires out of reach. He could scarcely agree with the views put forward by Mr. Hartnell in regard to the fire office. The rules were made for their own guidance, and not for the benefit of electrical engineers and contractors. He considered Mr. Hartnell had referred sufficiently to the question of bad joints, which was a frequent source of danger in houses in generating heat. Insurance offices, or the majority of them, had acted upon the rules of the Institution of Electrical Engineers, which were carefully drawn up. In conclusion, the speaker drew attention to accidents which might occur through leakage where moisture had fallen.

Sir FREDERICK BRAMWELL was not able to follow Mr. Hartnell in what he would call the basis of his paper. He understood it to deal with a certain size of wire as being competent to carry, and to continue to carry, for an indefinite time, and under all circumstances, a certain current of electricity without the danger of a certain temperature being attained. It seemed to him that the heat would be developed regularly during the interval of time, and the temperature would continue to increase until the dissipation of heat from the surface of the wire was carried off. It was doubtless wrong to give the size of wire to carry a certain heavy current without knowing the incidents of the surroundings of that wire. He would have liked to have taken one of Mr. Hartnell's wires and surrounded it with asbestos and then see what the result would have been. He thought the author of the paper omitted the very important consideration of the surroundings of the wire carrying the current, this should be taken into account. They could take a glow lamp and hold it in one's hand, but if they wrapped it in three or four thicknesses of handkerchief they would set it on fire. Therefore, in all these experiments the considering how far those who made the rules were reasonable in those rules, it was well to bear in mind the circumstances of the surroundings.

Major-General WEBBER referred to the rules drawn up by the committee of the institution, and said this was done to avoid any conflict. They laid down principles and left the bye-laws to be drawn up by the companies. He considered the prominence which had been given to the subject in the *Times* was to a certain extent detrimental to the industry. It made people imagine there was something very mysterious in the dangers likely to arise. Had the dangers of gas been placed before the public in the same way as the dangers of electric lighting, very little gas would have been in use. The rules in existence at the present time were amply sufficient for all purposes. He felt that the use of casing, except in certain cases, would gradually die out. The companies in insisting on casing between floors and ceilings were doing themselves considerable harm. The speaker then referred to the rules published in his British Association paper last year.

Mr. KAPP considered that although the current density rule was a very unscientific one, yet it worked very well in practice.

Dr. HARRIES, in reply to the criticisms passed upon his paper, said the resistance of the body depended on the contact and upon the state of moisture. Smaller currents unusually caused a great deal of pain, the larger one causing unconsciousness so quickly that no pain was felt. He did not propose to enter into the matter of execution, but they had a good deal to learn before they could safely say that a certain current would kill. The recent affair in America was, in his opinion, bungled in a fearful manner.

Mr. HARTNELL replied to remarks made upon his paper, but was indistinctly heard.

# TESTING IRON.

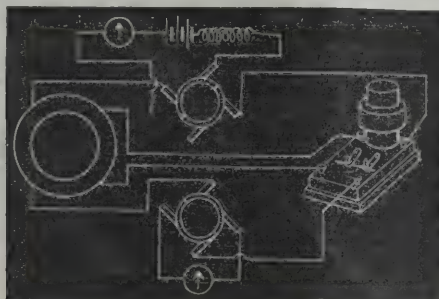

By J. SWINBURNE and W. F. BOURNE.

(Read before Section A, Leeds, September 9th, 1890.)

In practical work iron has to be tested as to its permeability and as to the loss by hysteresis. As regards permeability tests, the ordinary ballistic galvanometer method can, of course, be used; but a ballistic galvanometer is not a convenient instrument, and the method is too slow for practical use. It may, therefore, be of interest to describe the apparatus we use commercially. It is the development of a method devised in 1886. (See *Phil. Mag.*, July, 1887.)

The various samples of iron are obtained in the form of wire, and made up into rings, being wound on a former kept for the purpose, so that all the rings are alike as to dimensions. Before winding, the specific gravity of the iron is taken by weighing, and the specific resistance is measured. The ring is weighed to get the volume of iron, and is then wound with suitable primary and secondary wires.

The arrangement is shown diagrammatically in the annexed figure:—

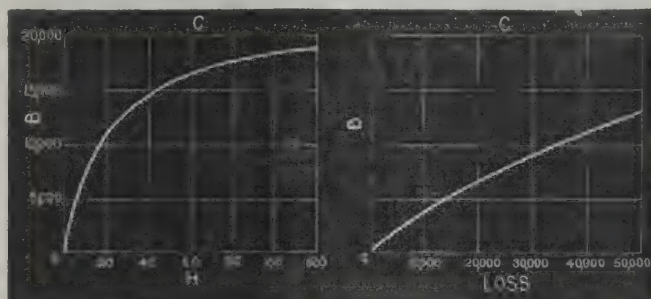

The circuit from secondary cells is led through an adjustable resistance, then through an ammeter to a commutator, resembling Brillouin's, which is driven by a belt from any shafting that may be near. The circuit is led through the primary to an induction box to the ring under test, and then back to the commutator. The circuit is then led back to the cells. The induction box consists of a primary coil, standing on end, and a number of secondary coils arranged so that the mutual induction is the same for all of

was taken, and put in the place of the sample ring, and its mutual induction measured with the induction box. To allow for the error due to the shortness of the cylinder of the standard coil, it was slipped out of the pilot coil, and moved exactly half its length in a direction along its axis, and a new reading taken. This reading gave the error due to the ends of the cylinder. A shunt was then put across the primary induction box, so as to make the readings come out in microhenrys.

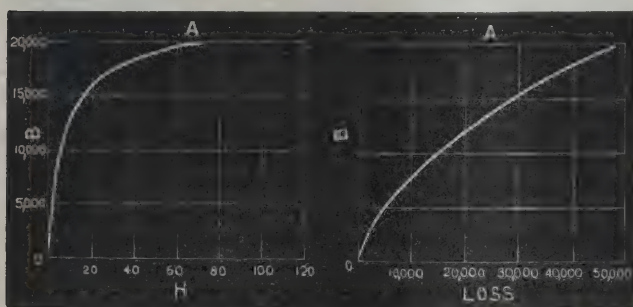

To test a sample of iron all that is necessary is to alter the mutual induction by steps, and to bring the galvanometer to zero for each step by means of the adjustable resistance. As the galvanometer is dead beat the readings can be taken in a few minutes.

The importance of loss by hysteresis in alternate current work is only now beginning to be fully realised. There are several ways of measuring the loss in transformers, but none of them seem satisfactory. Sometimes the transformer is put in a calorimeter, or else it is assumed that the pressure and even the exciting current vary harmonically, and have a so-called "angle of lag." The published efficiencies of most transformers are got by finding the loss from the copper resistances, and neglecting the loss in iron altogether. There is still another method, and that is taking the curves of pressure and current. Prof. Ryan has been singularly successful in this with a modification of Joubert's method.

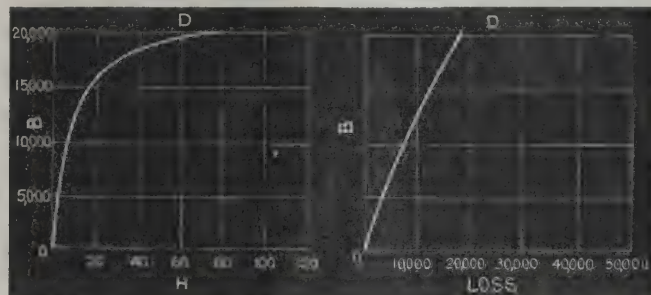

C.

Tests of transformers by means of lag angles and calorimeters have been published by Profs. Ferraris and Ayrton, and Major Cardew. As the loss in a transformer can be divided into the loss in the copper which varies as the square of the load, and the loss in the iron by hysteresis and Foucault currents which remains constant, these results can be checked. The results published,

A.

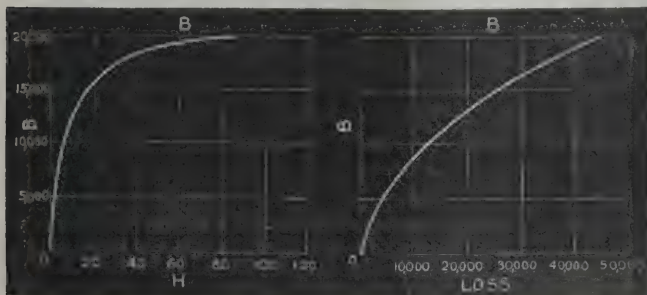

them. The secondary coils are led to buttons, and the switches include them by ones or tens, making the readings in steps of one per cent. of the highest. The primary of the sample ring is in series with that of the induction box. The secondaries are coupled so as to oppose each other, and arranged in circuit with a second commutator; a Varley, or, as it is more often called, a Deprez-d'Arsonval galvanometer, being inserted in the circuit. The two

D.

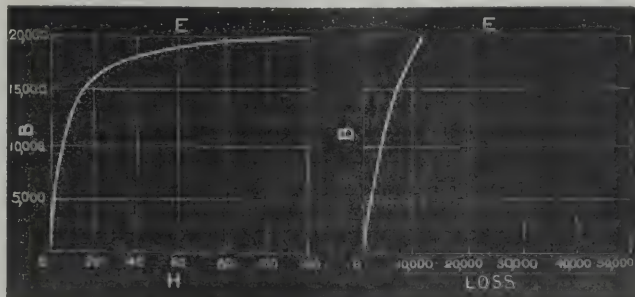

as obtained by these experimenters, show inaccuracies that make them quite valueless. The loss in the iron in Prof. Ayrton's experiments varies 160 per cent. of its smallest value, while Prof. Ferraris's cores give out power working as refrigerators. (See article "On Induction and other Things," *ELECTRICAL REVIEW*, October, 1887.)

There is really little reason for measuring the loss in a transformer; it is much simpler to measure the loss in the iron. No

B.

commutators are, of course, on the same spindle. The adjustment of the induction box was carried out as follows: The coils were roughly calculated to give a mutual induction a little in excess of a convenient round number per turn of secondary. A cylinder of a known diameter with a known number of turns per centimetre in the primary, and a known number of turns in the pilot coil

E.

one would think of measuring the loss in the copper by means of a calorimeter or angle of lag method. All that is needed is to measure the effective current and multiply its square by the resistance, the resistance being determined from the specific resistance of copper, or by direct measurement. Similarly, in the case of the iron, it is best to determine the qualities of the iron once for all,

and then the efficiencies of all transformers made of it can be foretold.

We use the same rings as for the permeability test, but do not employ the secondary wires. The loss of power at various frequencies and inductions is taken with a wattmeter. It is sometimes supposed that a wattmeter cannot be made with little enough self-induction to read accurately. If there is much self-induction in the pressure or shunt circuit, the reading will be lower than that with a direct current if there is no self-induction in the circuit in which the waste of power is to be measured; but if the current is behind the pressure, as in measuring the loss in iron, the wattmeter may even read too high. We therefore designed a special instrument, which was made for us by pupils of the London College of Electrical Engineers. The current coils are fixed, and the moving coil is suspended by a fine wire, with a fine spring at the foot, to take the electricity out again. The moving coil has few turns and little self-induction, and a large non-inductively wound resistance is in series with it. This wattmeter can be read with a mirror, if desired; but with 2,900 ohms in series with the pressure coil, it gives a torsion of  $2^\circ$  per watt on a non-inductive resistance. The series resistance is not wound with a looped wire as is usual in resistance boxes, because this method is not good, the insulation being apt to break down. A single wire was therefore used. When one layer was wound, the bobbin was reversed in the lathe, and the next layer wound in the opposite direction, a thin layer of insulation being put between the layers. This method secures absence of self-induction, and good insulation, as the beginning and end of the coil are kept well apart. The readings are taken by bringing the index back to zero by turning the suspension, so that the mutual induction of the coils is zero, as the coils are at right angles.

The self-induction of the pressure coil was not directly measured, as that would give us no useful information, as we do not know the variation of the current and pressure of air dynamos. They certainly do not vary harmonically, and at full load the pressure rises slowly and falls suddenly in each half period.

The wattmeter was therefore subjected to a severe test. Readings were first taken with direct currents on a resistance; readings were then taken on the same resistance with an alternate current. This resistance had very little self-induction, so that any self-induction in the pressure coil should lessen the reading, by making the current in the pressure coil lag, and also by reducing it. The reading with the alternate current was 2.1 per cent. less than with the direct. This figure is entered in the note-books, but though it is too small to matter in our work, it is larger than it ought to be. The next test was to measure the power taken by a coil with the same current and same pressure, but with no resistance and large self-induction. It is difficult to make up a coil with no iron core to take 50 volts and 10 amperes with no appreciable loss by resistance; we therefore took a hedgehog transformer, and measured the power taken by it. The reading was taken with 50 volts and 4.2 amperes. If the pressure coil had any appreciable self-induction, the reading would be considerable; it might, in fact, be anything up to about 200 watts. The least self-induction would increase the reading enormously. The reading was 11 watts, and the calculated loss by copper and iron in the transformer with only 50 volts on its secondary was  $10.3$ ; so the wattmeter is practically correct. Let it be supposed, however, that the loss in iron was really less than this, and that the loss was two watts less than the reading. This is an extreme assumption; but we may see how much such an error would affect our readings of the sample rings. The assumed error is 1 per cent. of the product of the pressure and current. Now, in the case of a closed iron circuit the power is about half the product; so this would lead to an error of 2 per cent. in the loss in the iron. In a closed circuit transformer the loss in iron is, roughly speaking, 10 per cent. at full load, and about 40 per cent., to take a low figure, taken over the day; so that the error would be 0.2 per cent. and 1 per cent. In the hedgehog form the loss in iron is about 1.5 per cent. at full, and 15 per cent. at all day loads; so the errors are .03 and 0.3 per cent. respectively, which are too small to matter. As a matter of fact, they are much less than the various errors of observation that creep into such work. Measuring the power in an open circuit transformer is also a most difficult case, for the least self-induction then gives rise to the largest error; in measuring the power in a closed circuit ring the errors are less.

We give a number of curves of permeability and of  $f \times d \times q$  per cubic centimetre for different samples of iron. These are practically the same as curves of  $f \times d \times h$ ; but  $f \times d \times q$  seems a better way of writing it, as  $f \times d \times h$  can scarcely be said to have any physical meaning, and has even had the effect of not suggesting that the reversal involves waste of energy; indeed, it seems to have rather disguised the fact.

In completing these curves some corrections have been made. The wattmeter absorbs some power itself, as the pressure coil circuit is led through the current coils. We might have compensated for this in one of the ways described to Section A by one of us in 1887, but in this case did not think it worth while. The Foucault current losses are also corrected. The losses in the wires themselves can be calculated with rigid accuracy, as explained in a paper on "Transformer Design," which one of us had the honour of reading before Section G last year. There might also be some loss by Foucault currents, due to imperfect insulation between the wires of the core. The insulation is, however, too good to allow this; in fact, the resistance between two wires, about an inch apart, runs into ohms, the measurement being seven ohms in the particular example taken. The losses by Foucault currents are frequently over-estimated by writers on the

subject. If the specific resistance of the iron is known, they can nearly always be calculated with much greater accuracy than they can be measured. The loss by the copper resistance is also allowed for in the curves. Though it is generally the practice to give all the steps in a paper like this, we think it better to give the results only; for, though the paper then looks less imposing than if full of curves and calculations, it is more likely to be useful.

We have not yet tested the same sample at very different frequencies to see if there is any time lag. From the comparatively small loss at high frequencies, it is not probable there is any appreciable time lag.

#### THE EFFECT OF OXIDATION ON THE MAGNETIC PROPERTIES OF MANGANESE STEEL.

By L. T. O'SHEA, B.Sc.

(Abstract of Paper read before Section A, September 9th, 1890.)

WHEN manganese steel drillings are oxidised they become magnetic. The development of magnetic properties being due to removal of manganese by oxidation, &c., to the magnetic properties of the oxide of iron (probably magnetic oxide) formed.

When the oxidised product is reduced in hydrogen the iron oxide is converted into metallic iron and the manganese remains as manganous oxide ( $MnO$ ). The reduced steel is now powerfully magnetic in virtue of the magnetic properties of unalloyed metallic iron.

During the process of oxidation the proportion of manganese to iron oxidised in a given time is only very slightly in excess of the proportion of manganese to iron in the original steel. The excess of manganese oxidised is in all probability due partly to the greater susceptibility of manganese to oxidation, and partly to the heterogeneous structure of the steel.

The following discussion was conjointly on Messrs. Swinburne and Bourne's paper on Testing Iron; Mr. Preece's paper on Magnets, and Mr. O'Shea's paper:—

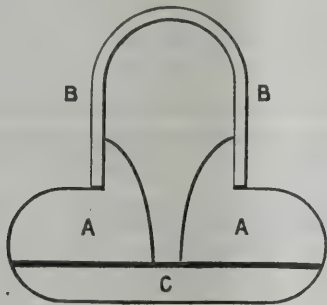

MR. PREECE said it was his intention to pursue the question of tempering, and he would be thankful for any suggestions. He was going to take a great number of samples of steel, raise them to different temperatures, and quench them in different cooling mixtures, such as oil, mercury, and water.

Prof. BARRETT remarked that he believed the exact temperature at which the heated steel was hardened by quenching, as well as the ratio of quenching, would be found to be important. If quenched short of the recalescent point no hardening ensued, and steel could not be tempered; hence the subject connected itself with the Committee, of which he was secretary, on magnetic and other phenomena connected with the recalescent point in steel. Dr. Ball in a recent paper read before the Iron and Steel Institute, said that both the tensile strength and magnetic properties of steel underwent a constant change when the steel was quenched at a too critical point; one  $700^\circ C$ ., and the other about  $1,300^\circ C$ . He hoped Mr. Preece would send specimens of his steel to the recalescent committee. In regard to Mr. O'Shea's paper, Prof. Barrett remarked it was Mr. Hadfield who first noticed that magnetic steel filings became magnetic in heating to whiteness. He had, through Mr. Hadfield's kindness, been able to make many experiments on this question, the results of which he had communicated to the Royal Dublin Society. Mr. O'Shea had shown that oxidation could hardly be regarded as sufficient cause, and he (Prof. Barrett) was inclined to think the cause was due to some dissociation or decomposition of the magnetic steel, whereby free iron particles were liberated. This effect did not occur in wire nor in filings wrapped in platinum foil; but this might be explained by the more rapid cooling which takes place in the filings, whereby the molecular state at a high temperature might be fixed.

MR. O'SHEA, in reference to Prof. Barrett's remarks on dissociation, pointed out that steel in the mass did not present those magnetic properties to the same extent as it did in the filings, and why should dissociation take place in the filings when it did not in the mass? His point was that oxidation did take place, but in the case of a mass of steel that oxide scaled off and left the metal perfectly free from oxide; whereas in the case of the filings the oxide remained with them, and they remained magnetic; then it was that dissociation took place. When the two were oxidised they first had the oxide of iron exerting its magnetic effect, and then, after reduction, the metallic iron exerted its magnetic effect.

Prof. PERRY said that there could be no more useful work than that which was being undertaken by Mr. Preece and his assistants, and as Mr. Preece subjected all the specimens to the same treatment his test was a fair one. But was this the same in the matter of tempering. He gathered that only one English specimen was tempered in mercury, and the Allevard specimen had not been tempered by Mr. Preece. He put it that this was really the important matter, the tempering, and he was glad to think that Mr. Preece intended to go thoroughly into the effect of tempering. Until that was done these results were useless. He (Prof. Perry) had tempered differently three similar specimens of the same steel. One in water, one in a little mercury, and one in a large bath of mercury. The third had an enormously greater retentiveness (he was not sure, but he thought it was three times) than the first.

He had the notion that steel must remain in a magnetic circuit of small magnetic resistance if it is to retain its induced magnetisation. That is, suppose a nearly complete ring of pieces of steel to have been magnetised, the magnetisation would be greatly diminished by taking them apart and replacing them. He obtained his great permanent induction by using the best form of magnet he could think of for that purpose, although it might be useless for all other purposes (fig.) B was a strip of glass-hard

steel, fitted to soft iron pole pieces, A A, C being a well-fitted keeper. The force required to pull off the keeper enabled the induction to be calculated. As the dimensions were great at right angles to the keeper, it was obvious that whether the keeper was on or off there was always extremely little total magnetic resistance.

Sir Wm. THOMSON said that Mr. A. Gray and himself had made a large number of experiments in the physical laboratory of the Glasgow University comparing steel from different makers. It was very difficult to get from the same maker constant results. Over and over again the specimens were found to differ exceedingly in magnetic quality from one another by 10 or 20 per cent though alleged by the maker to be as nearly the same as he could make them. On the other hand, they would get a very good specimen, and would ask for one like that, but had very great difficulty in getting what they desired. The specimens could not be too hard, and even when he asked for them to be glass hard, those sent did not come up to what he knew they ought to have. He returned them to be made as hard as they could be made, and only then did he get good results. He was exceedingly glad that Mr. Preece had taken the subject up, and he thought the results would be exceedingly valuable and interesting, not to science only, but to applied science. There was a great career for steel magnets.

Mr. GRAY remarked that the induction obtained by Sir Wm. Thomson and himself was about 12,000.

Sir Wm. THOMSON said that they reckoned the standard result for the very best steel used to be 100 C.G.S. intensity of magnetisation per gramme weight; that corresponded to only about 10,000 induction, and he was pleased to see the results put forward by Mr. Preece were enormously better than what was supposed to be obtainable. C.G.S. per gramme was a very convenient way of putting it. In connection with his experiments he multiplied by the specific gravity of steel 7.8, so that 100 magnetic moment per gramme gave 780 magnetic moment per cubic centimetre intensity of magnetisation, and that was the best way of putting it. This was the highest intensity of magnetisation that could be obtained.

#### THE LINEFF ELECTRIC TRAMWAY.

By GISEBERT KAPP.

(Read before Section G, September 8th, 1890.)

The following is an abstract of the paper read, a fuller description was given in the ELECTRICAL REVIEW for July 4th, 1890.

The conductor consists of bare copper strip or cable, and of iron strip. The latter is galvanised so as to protect it from rusting. It lies on the copper conductor, and both are enclosed in a sealed channel formed of asphalt. The copper conductor rests upon the bottom of a trough made of a succession of glazed tiles, and the cover to this trough is formed by the lower flanges of iron rails arranged in short sections so as to be insulated from each other. The head of one rail reaches up to the surface of the road, the head of the other is cut off, and this rail is therefore completely buried in the asphalt. The surface rail, which may be arranged alongside one of the ordinary tram rails or in the centre of the track, is in electric and magnetic contact with an electro-magnet carried under the car. This magnet runs upon the surface rail on wheels which form its north and south poles. The distance of the wheels is greater than the length of a section of insulated rail, so that successive sections become oppositely magnetised. This causes the iron strip immediately below the magnetised region to be attracted upwards, and thus come into contact for a length of several feet with the under side of the two sectional rails. At the same time the iron strip to both sides of this region remains in contact with the copper conductor, and forms thus an electrical connecting link between the copper conductor and a few sections of insulated rail under the car. The current passes from the surface rail through the body of the electro-magnet (which is insulated from the body of the car) into the motor, and finally into the ordinary tram rails and earth in the usual manner. The electro-

magnet is energised by a shunt current obtained from the main conductor, but to provide for the possibility of dropping the strip from some unforeseen cause, there is placed on the electro-magnet a third thick wire coil, which can at all times be energised by two storage cells carried on the car, and thus the strip can be picked up and the main circuit again established if it should have been accidentally interrupted. I may, however, at once state that during some tests which I made on an experimental line of this kind, and which lasted over several days, there has been no need for the picking-up battery, as the current was never lost. The way in which Mr. Lineff makes use of magnetic lines of force to effect the attraction of the iron strip deserves attention. It might perhaps be thought that the most direct, and therefore the best, way of utilising the lines of force would be by one single line of sectional rail, through which there would be longitudinal magnetic flux corresponding with the fore and aft position of the poles, and attraction of the strip at every gap between two sections. Experiment has, however, shown that this apparently direct way is by no means the best way, and that far more satisfactory results can be obtained by arranging a more roundabout course for the lines of force. This is attained by the employment of the subsidiary or buried rail, the gaps in which do not exactly correspond with those in the main or surface rail, but are shifted forward by a certain amount. In consequence of this arrangement, the buried rail acts as a kind of magnetic bridge to successive portions of the surface rail, and this action takes place in two ways, one direct and the other indirect. The direct way is longitudinal, and does not affect the strip at all. The indirect way is both longitudinal and transverse, the latter passing several times through the strip. The buried rail is a rather imperfect bridge to the lines of force traversing it longitudinally, because its magnetic resistance in that direction is great, but this rail forms a very efficient bridge for lines passing through it transversely, owing to its lower magnetic resistance in that direction which includes the strip. The flow of magnetic force transversely is therefore that which effects the attraction of the strip, and may be represented as a series of magnetic stitches passing to and fro between the two sets of rails and the strip.

#### DISCUSSION.

Major-General WEBBER said they were very much indebted to Mr. Kapp for his description of the system. It was one which, he thought, met, in a remarkable way, a want which had been felt for a long time, assuming, of course, that nothing but underground conductors would be allowed by the authorities. Several engineers of the speaker's acquaintance had been directing their attention to the means of picking up contact in a duct underneath the surface, which contained the copper conductor, and they had, he must confess, fallen short of the ingenuity displayed in the system suggested by Mr. Lineff. The description he had just heard showed that they might see daylight in that direction. He should like to draw the attention of Mr. Kapp to one or two points, on which the meeting was entitled to a little further information. Before proceeding further, the speaker pointed out one or two things, on the diagrams, which were not quite clear. In the main, however, the diagrams gave a most excellent and graphic description of the way in which the magnetic field in the rolling magnet excited the rail. He felt, however, that there was absence of information as to the pressure which actuated the motor in the car. Supposing the pressure to be five volts, he failed to see that it was secure in preventing the rail remaining in contact after the passage of the car travelling at the rate of about 15 miles an hour, not particularly on the lines, but in the subways. Although the people did not walk in the subways, there was still a liability to accident if there resulted a permanent contact between the strip and the iron rails. In the absence of that information, he would also like to ask the size of the copper conductor to the work which requires to be done. He must confess some doubt as to the insulation of the conductor as shown on the diagram. Though it might be fairly good, there was the different condition of highways, &c., and the question of weight, which at some time might break the whole thing to pieces. In conclusion, the speaker referred to the competition between the use of cable and electrical traction, considering there was a large field for work.

Mr. PREECE said he had only to add to what Mr. Kapp had said by stating that he had inspected the working of the system near Chiswick, and he corroborated every word that the reader of the paper had said. His (the speaker's) fears of practical success of the system were, principally, that there might be a failure of contact; but this was got over, first, by having a very broad strip and very lengthy contact, and also by the fact that the flexible iron conductor is galvanised, and, therefore, always clean. Moreover, the galvanisation on the surface has exactly the same effect as the insertion of pieces of paper on the pole pieces of electro-magnets. Of all systems produced, this had an air of practicability about it, but it would be quite impossible to give a definite opinion upon it until it had received the test of actual practice. His impression was that the tramway company which served the district about Kew would lay down three or four miles of the system, and he hoped when they met at Cardiff next year that Mr. Kapp would be able to tell them the results of an absolute practical test.

Prof. ARNOLD LUTON said some remarks on the insulation of the rails and the falling of the strips, but his remarks were indistinctly heard.

Mr. SELLON said there were one or two questions he would like

to ask. They had not had any detail as to the cost, which was naturally the first thing of a tramway engineer. Although Mr. Kapp had said the system could only be an advantageous system in the particular districts, because no other would be allowed in the districts, he did not see why other electric systems should be thrown out, because Mr. Kapp wished to introduce Lineff's system. He would have been glad if Mr. Lineff had joined hands with them in the late fights in Parliament against telephone companies. If the telephone companies were going to have their clauses introduced into their bills for electric traction, neither Mr. Lineff's system nor any other system by which the return wire coming through earth could be used. One great difficulty he saw with the system is whether the contact is always going to drop directly the car passes over at great speed. He desired before sitting down to draw Mr. Kapp's attention to the telephonic clauses, and he asked the question as to the cost per mile and its absolute efficiency from its generating station at the car motor.

Prof. EWING said how much one must admire the exceedingly ingenious method by which Mr. Lineff had solved the fundamental magnetic difficulty in the problem. They had here a strip of sufficient amount of mechanical force; the action upon the iron strip occurred only when the iron rail above it was interrupted, and if the longitudinal action had been made use of, it would have been necessary to cut a longitudinal rail into an inconveniently large number of sections, but by the exceedingly simple device of employing a supplementary rail cut into comparatively long sections, Mr. Lineff had succeeded in grasping his conductor not at one or two points only, but almost the whole length under the car. It was impossible not to admire, from the magnetic point of view, the exceedingly ingenious solution of the difficulty. Something after the same system had been before the public as a proposal for a number of years—namely, the system originally introduced by Messrs. Ayrton and Perry having a thoroughly well insulated conductor underground, which was to be connected when the car passed with successive sections of a not so well insulated conductor serving as a service conductor. This was exactly what Mr. Lineff did, though, of course, in a very much more satisfactory way than the mechanical methods practised by Ayrton and Perry.

Mr. SWINBURNE wished to emphasise what Mr. Sellon had said. It was an important question that of the telephones, and one hardly knew what would happen unless the thing could be settled. Insulated returns were insisted on, which was a tremendous drawback to electric traction.

Major-General WEBBER said that, with regard to the telephone, they could next year dismiss this fear from their minds, for he had every reason to believe that almost all the telephone systems in this country would be served by metallic returns and not by earth returns, in which case it would not be necessary to insist on such clauses.

Mr. KAPP, before entering into the technical questions, said he would reply to Mr. Sellon. He wished it to be clearly understood he had not any interest whatever in bringing forward the Lineff system. He placed before them the result of careful investigations without comment. He did not wish, as Mr. Sellon had said he wished, to throw out any other system of electric traction; for his part, he would be glad to see it go ahead a little faster. English Town Councils (and they must reckon with the powers that be) would not tolerate the overhead wires, and, consequently they must work with the underground or some other system, and often the Town Council, as was the case in the Hammersmith Vestry, had so tender a regard for cyclists, as to prohibit the use of the slot in the street. The difficulty in disturbing the telephone wires were overcome by working the tram lines on the three-wire system, the down line connected with the positive and the up with the negative, and the third wire put to earth, which resulted in a differential current, which was small, going to earth. He was sorry that he did not explain that the current went back to the station in the usual way; but, of course, they could have a second conductor if they wanted to work a close circuit. The system of duplicating the telephone wires was far preferable. They all knew the bad telephones in London, and they would be better if that plan were adopted. In regard to the question asked by General Webber about the strip remaining in contact, he was sorry he did not make it quite clear; the strip did not remain in contact. He had a fear that the residual magnetism would be enough to heat the strip, and another fear was the main wave under the car, by some way jerking the strip, would induce subsidiary waves and make a contact; but he (the speaker) had tried in many ways to make this contact, but had not succeeded. General Webber evidently thought the contact would be due to the voltage, but the residual magnetism did not prolong the contact, which was the reason that galvanised covering was used. As to the enquiry about insulation, what he had put on the blackboard is the line as it was actually built, but since the line had been finished Mr. Lineff, who had a most ingenious mind, had improved the general arrangement of the surface, and hoped thereby to get a very much higher insulation. As to failure of contact, a part of Mr. Lineff's work was to provide means whereby the strip could be drawn out and a new strip drawn in, if it were found the strip fell down. A gentleman on the left asked how this one-car system could be worked. The system of working tramways most in use was known as the parallel working system. The conductor which brings the current was tapped by each car, which drew off sufficient current to give motive power; but there was nothing to prevent the second car tapping the said conductor. It was a well-known system of

tramways, which had been used in many cases. An ascending car would tap off a little more electric fluid, if he might be allowed to use an unscientific term, and a descending car may tap off a little less, or it may give back a little, if the descent was strong enough. As to whether there would be any noise from the strip, there would be absolutely none whatever. As to the question of cost, he knew what Mr. Lineff's estimate was, although he did not know whether it was correct, the cost would be £2,000 a mile, which was a little heavier than overhead conductor, but not much.

#### COLUMN-PRINTING TELEGRAPH.

By F. HIGGINS.

(Abstract of paper read before Section G, September 9th, 1890.)

This apparatus was originally patented 10 years ago, and is now being practically introduced for the transmission of intelligence in this country.

The receiver, which is entirely automatic, consists of a type wheel and frame carrying the paper sheet. The former derives the motive power for its rotation from a train of wheelwork and a weight, and the latter from the battery at the sending end.

The type wheel is displaced laterally, after each print, by means of a screw, and upon completion of a line of printing is released and returned to zero by a spring which has been wound up by the movement of the printing lever.

One train of clockwork is employed, and the motive power for printing, feeding the paper, and traversing the type wheel, is supplied by the printing electro-magnets.

About 20 of these instruments may be introduced into the circuit of a single line of wire, and any number may be worked from one transmitter. The type rotates at any desired speed (from 100 to 150 revolutions per minute), and the same signals operate both the type rotation and the printing, the difference being that the signals for printing are longer than those operating the escapement, in order to afford time for the establishment of the full strength of the current in the circuit, and to overcome the inertia of the comparatively heavy parts of the printing mechanism.

The other operations of synchronising, spacing between lines, &c., are determined by the angular displacement of the type axis with respect to its zero position. The transmitter is driven by an electro-motor, the speed of which is kept uniform by an electrical governor. A counter upon the transmitter announces to the operator when a line of type has been filled. From 1,800 to 2,000 words per hour would be the maximum speed. Five thousand words can be received without attention, and the paper supply is sufficient for the reception of 30,000 words.

#### THE EFFECT OF DIRECT AND ALTERNATING PRESSURES ON THE HUMAN BODY.

By J. SWINBURNE.

(Read before Section A, September, 1890.)

As there seems to be some doubt as to the relative effects of alternating and direct currents, a bridge which measured the resistance of the patient under various pressures was made up. Fuller readings, which agreed with the first as nearly as such very uncertain readings can be expected to agree, were afterwards taken by putting on different pressures and measuring the current; the resistances being calculated. The alternating currents were measured with a non-inductive wattmeter arranged as an ammeter, the pressure being taken with a hot wire voltmeter. The tests were taken from hand to hand, the hands being dry or wet with dilute acid in the case of direct currents, and dry in the case of alternating. It seemed to make little difference in the case of alternating currents whether the hands were wet or dry. There was no need to measure the resistance from hand to foot, as that obviously would depend on the boots worn.

Human Resistances; Hand to Hand..

Current.	Name.	Hands.	Volts.	Resistance.
Alternate ... ..	A	Dry	18	950
Continuous ... ..	"	Dry	50	8,000
Continuous ... ..	"	H <sub>2</sub> SO <sub>4</sub>	50	8,010
Alternate ... ..	B	Dry	10	1,330
Alternate ... ..	"	Dry	18	1,110
Continuous ... ..	"	Dry	50	6,660
Continuous ... ..	"	H <sub>2</sub> SO <sub>4</sub>	50	1,930
Alternate ... ..	C	Dry	18	620
Continuous ... ..	"	Dry	50	5,400
Continuous ... ..	"	H <sub>2</sub> SO <sub>4</sub>	50	1,980
Alternate ... ..	D	Dry	18	1,090
Continuous ... ..	"	Dry	50	10,000
Continuous ... ..	"	H <sub>2</sub> SO <sub>4</sub>	50	16,000
Continuous ... ..	E	Dry	50	6,700
Continuous ... ..	"	H <sub>2</sub> SO <sub>4</sub>	50	1,100
Alternate ... ..	"	Dry	18	1,300
Alternate ... ..	F	Dry	18	750
Continuous ... ..	"	Dry	50	3,320
Continuous ... ..	"	H <sub>2</sub> SO <sub>4</sub>	50	1,710
Alternate ... ..	"	Dry	54	670

In the above table the direct pressure is always 50 volts. Any of those tested could have taken more than this; but even with 50 volts the discomfort is extreme if the contact is made and broken. The maximum current taken was .04 ampère by E, whose resistance is low. He could have taken more if available. All the resistances are much lower than those obtained by the usual method of measuring with a bridge and one or two cells. Probably polarisation then interferes.

When the direct current from 50 volts is concentrated in one finger it feels hot, though especially as the current is reduced, there can be no appreciable heat generated.

The most curious thing is the very low effective resistance to alternating currents. The alternating pressure could be regulated by steps of 4.5 volts. Out of the five subjects tested not one except F could stand more than 18 volts alternating, the maximum effective current taken being .03 ampère. F seems abnormal. He took 54 volts and nearly a tenth of an ampère. D, who has the highest resistance, was the only lady tested. Though, with the exception of F, none of us could take more than 18 volts alternating with a good contact, I have several times touched 600-volt alternating terminals lightly. They were given by a Siemens machine used for "flashing" lamps. Before I took charge of the factory containing it, I am told several of the girls had shocks from the same machine. Spring switches, which demanded both hands to give any current, obviated danger to them afterwards. I have also had a very severe shock from a 100-volt Ferranti. Though 18 volts was as much as we could take, there was no difficulty in letting go.

These results bear out those of Messrs. Lawrence and Harries + as to the relative resistance to alternating and direct currents, but the figures are entirely different. They never found anyone take over 10 milliampères, while F took 90 milliampères alternating, and E, a workman, took 44 milliampères direct, and could have taken more if available.

13799. "Improvements in electrical signalling apparatus." H. H. LAKE. (Communicated by the Electric Secret Service Company, United States.) Dated September 2. (Complete.)

13845. "Improvements in and relating to the propulsion of tramway vehicles or boats by means of electricity." J. L. HUBER and L. J. MAGEE. Dated September 3.

13886. "Improvements in and connected with the distribution of power by alternating electric currents." J. SWINBURNE. Dated September 4.

13897. "Improvements in apparatus for the safe deposit of milk and other articles; for electrically announcing the same, and for saving and registering time." C. E. KELWAY and A. KAPADIA. Dated September 4.

13905. "Improvements in and relating to the welding of metals by electricity." M. W. DEWEY. Dated September 4. (Complete.)

13921. "Improvements in electric lamps." A. SCHANSCHIEFF. Dated September 4.

13943. "Improvements in power conduits for tramways or railways and in electrical connections therefor." C. T. B. BRAIN. Dated September 4.

13987. "An electricity counter." J. RICHARD, F. RICHARD, and G. RICHARD. Dated September 5.

14050. "An improvement in electrical cut-outs." SIEMENS BROS. AND CO., LTD. (Communicated by Siemens and Halske, Germany.) Dated September 6.

14054. "Improvements relating to apparatus for converting alternating electric currents into continuous currents." W. S. RICHARDS and G. B. JAMES. Dated September 6.

## ABSTRACTS OF PUBLISHED SPECIFICATIONS, 1889.

10082. "Improvements in insulating bases for electric switches, fuse blocks, ceiling plates, and the like." G. BINSWANGER. Dated June 20. 8d. The inventor provides china bases with projecting walls vertically disposed on the front, top, or outer surface of said bases, and forms these vertical walls with perforations or holes through which the metal screws are passed for securing the metal conductor. 5 claims.

11046. "Improvements in cores for electrical apparatus and the method of forming the same." W. P. THOMPSON. (Communicated from abroad by The Westinghouse Electric Company, of America.) Dated July 9. 8d. Consists in first stamping from sheets of suitable magnetisable material such as soft iron, plates of the required size and form from which to build up the core; then subjecting the plates to an annealing process which is carried to such an extent that a thin film of oxide is formed over their entire surfaces, and over, also, the burrs or rough edges produced by the stamping process; and afterwards building up the core by placing such plates side by side. 4 claims.

11242. "Improvements in dynamo-electric, magneto-electric, and electro-dynamic machines." SIEMENS BROTHERS & CO., LIMITED. (Communicated from abroad by the firm of Siemens and Halske, of Berlin.) Dated July 12. 11d. Relates to improvements in dynamo-electric, magneto-electric, and electro-dynamic machines, such as were described in the specification to patent No. 1447, of 1881, wherein a continuous current was produced by separate electrical impulses generated immediately after one another at different parts of the machine, that is to say, in different magnetic fields, the number of rotating bobbins in the form of solenoids being different from that of the magnetic fields, so that the former did not all pass the latter simultaneously, but at successive intervals. The present improvements relate to a modified form of the bobbins (which formerly were made as solenoids), wherein these are made of a zig-zag form with radial active and circular inactive parts. 2 claims.

11296. "Improvements in appliances for setting up or taking down electric incandescent lamps." The Honourable H. DUDLEY RYDER and H. E. DOPSON. Dated July 13. 8d. In order to enable an attendant to so place the stem of an electric incandescent lamp into the socket which is to hold it without the attendant having to get into close proximity to the socket, the inventor provides a holder within which the glass of the lamp can be held and be retained by friction to some extent from turning therein. 3 claims.

11332. "An improved material for the construction of bearing surfaces specially applicable to the brushes and commutators of dynamo-electro machines." K. W. HEDGES. Dated July 15. 8d. Relates to the manufacture of a new material for rubbing or bearing surfaces composed of a mixture of carbon and mica or steatite. 2 claims.

11501. "Improvements in the construction of electric fuzes and detonators, and in the method of and appliances employed for manufacturing the same." P. WARD and E. M. GREGORY. Dated July 18. 8d. Has for its object to provide a means of more completely protecting the fuzes from the destructive influence of moisture, heat, climatic and other influences. 3 claims.

## NEW PATENTS—1890.

13319. "Improvements in electric bells and motors." J. TOWNLEY. Dated August 25.

13337. "Improvements in electrical contacts." G. FORBES. Dated August 25.

13357. "Improvements in electro-motors." A. SIEMENS. Dated August 25.

13358. "Improvements in the means for driving winches and other winding machinery by electrical motors." A. SIEMENS. Dated August 25.

13359. "Improved means for carrying electro-motors on electrically propelled cars or vehicles." SIEMENS BROTHERS & CO. (Communicated by Siemens and Halske, Germany.) Dated August 25.

13371. "Improvements in electric bells and indicators." H. J. HARRIS and W. H. POWER. Dated August 25.

13421. "Improvements in apparatus for working or welding metals electrically, and in the method of effecting the same." W. P. THOMPSON. (Communicated by C. L. Coffin, United States.) Dated August 26.

13485. "Improvements in fittings for electrical glow lamp conductors." W. WHITE. Dated August 27. (Complete.)

13525. "Improvements in electricity meters for alternating or interrupted currents." G. HOOKHAM. Dated August 28.

13535. "Improvements in electrical alarms." N. G. THOMPSON and G. H. REW. Dated August 28.

13549. "Improvements in and relating to converters of alternating currents." R. KENNEDY. Dated August 28. (Complete.)

13570. "Improvements in and relating to telegraphic apparatus." B. EGGER. Dated August 28.

13635. "Improvements in or appertaining to electric welding." W. P. THOMPSON. (Communicated by C. L. Coffin, United States.) Dated August 30. (Complete.)

13636. "Improvements in electric welding." W. P. THOMPSON. (Communicated by C. L. Coffin, United States.) Dated August 30. (Complete.)

13683. "Improvements in electric switches." O. ROMANZE and F. W. WHITE. Dated August 30.

13751. "Improvements in electric switches." C. W. HUNTINGTON. Dated September 2. (Complete.)

13770. "Improvements in systems of electrical distribution of light and power by means of transformers." W. F. TAYLOR, G. B. LUCKHOFF and E. H. HUNGERBUHLER. Dated September 2.

13774. "Improvements in electrical connections." F. C. DUNAWAY and F. W. DUNAWAY. Dated September 2.

13791. "Improvements relating to compositions and devices for use in the manufacture of filaments for incandescent electric lamps." H. H. LAKE. (Communicated by V. M. Hobby, United States.) Dated September 2. (Complete.)

14342. "Improvements in or relating to accumulators or secondary batteries for use in lighting railway carriages and other conveyances by electricity." J. C. MEWBURN. (A communication from abroad by La Société Anonyme pour le Travail Electrique des Métaux, of Paris.) Dated September 11. 8d. Relates essentially to:—1. A trough lined with a vessel of insulating material, and hermetically closed. 2. Accumulator plates having a special appendage either for individual grouping of plate to plate of the same category, or for the grouping of apparatus to apparatus. 1 claim.

14656. "Improvements in electric glow lamps." A. BERNSTEIN. Dated September 17. 6d. The current is conveyed from two platinum wires which are sealed into the glass bulb. From the platinum wires the current passes to the carbon by means of stout conducting wires, which are generally made of nickel. These conductors are bent in such a manner as to almost approach each other at a given point, and they are held rigidly apart by means of a glass or other insulating piece at their lower end, near to the point at which the conducting wires are attached to the platinum wires. A part of one of the conducting wires is hammered out flat, and thereby forms a spring, which has the tendency to produce a contact between the conducting wires at their bent portion. The conducting wires are held rigidly apart at their two extreme ends, first by means of the glass insulating piece, and, secondly, by means of the carbon rod, as long as the latter is intact. If, however, by the action of the current the carbon should be destroyed, then the conducting wire, which is flattened out as a spring, will follow its tension and produce an automatic short-circuit by placing the conducting wires in contact. 2 claims.

17762. "Improvements in electrical switches." F. L. RAWSON and W. WHITE. Dated November 7. 6d. The inventors enclose an electrical switch of any suitable form in a case of metal or other watertight material having stuffing boxes in its sides, through which pass the insulated conductors to the switch terminals. The top of the case is conveniently formed as a cover, which screws on to the lower part with a face and groove for packing to render the joint water or gas tight; in the centre of this cover is a stuffing box through which passes the handle spindle. This handle spindle has the handle attached to it outside the cover stuffing box and inside it is formed so as to engage with the switch contact arm through an insulating piece when the cover is in place; but this coupling is free and is arranged so that the cover with the handle spindle and handle is quite free to be taken off without interfering with the switch contact arm. 1 claim.

18897. "An improved quick-make and quick-break switch for electrical purposes." J. G. S. CUNNINGTON. Dated November 25. 6d. Consists of a lever and spring, which in the first part of their movement are acted upon or controlled by the handle of the switch. In the remainder of their movement the spring acts on the lever to which one end is attached and draws the lever forward independently of the handle of the switch. 3 claims.

19129. "Improvements in electric dry batteries." C. R. BONNE. (Communicated from abroad by H. Meinecke, the younger, of Breslau.) Dated November 28. 4d. Consists in saturating the carbon electrode in sulphate or nitrate of silver, and in bringing it in contact with sal-ammoniac or with other liquid or substance saturated with liquid in order to form chloride of silver, which is deposited in finely disintegrated particles on the carbon. 1 claim.

## THE POSTMEN'S STRIKE.

CONCEIVED in frenzy, characterised by indecision and terror, and carried out in anything but a spirit of general unanimity, the postmen's strike appears, for the time being, to have drifted into the leeway of current topics. The variety and chameleon-like changes in these latter-day struggles between capital and labour are, doubtless, responsible for the little notice taken of the terrible position to which the unwise and unhappy postmen now find themselves reduced; but we are glad to note that the subject has not been altogether lost sight of by the Press, close upon 400 men are realising now all the terrible disadvantages and misery of an unsuccessful strike, their position rendered all the more gloomy from the fact that they are reduced to a much lower level than that touched by artisans and tradesmen who adopt similar courses in fighting for the cause of labour.

When the working man strikes, which he does almost invariably as a matter of business and not of sentiment, there is no avenging angel of monopoly to bolt the door for ever in his face, and to enact a decree of commercial banishment against him. Hard as the fight may be, bitter as recriminations oftentimes are,

yet the character and manhood of the individual are, generally speaking, in no way involved, and on the settlement, successfully or unsuccessfully, of differences between master and man, the old faces and the old hands "go in," and if there is not exactly joy in the manager's office, at all events, there is no desire to indulge in reprisals; and this is as it should be.

Another most important feature is that the tradesman or artisan need not tie himself to any one shop, factory town, or district. His passport is his tool-bag, and his ability as a workman is a certificate which will carry him round the whole wide world.

He makes light often of the fact that he has been a decade, or, perhaps, two, with some respected master. His departure from the old bench means no loss of pay or social position. It may be the result of circumstances over which neither he nor his employer has any control; besides, few good men remain idle long. The master, indeed, may pay him off through slackness of trade or through the closing of contracts. But it may be that the next influx of work will find him back at his bench, if he has not "gone in" elsewhere. Some men, indeed, do not care for permanent situations.

As much is to be learned by travelling, so will intelligent men often find a means of coming to the front in their callings through the experience begotten of a discreet course of changes from shop to shop or from factory to factory.

We mention such matters to show that to the workmen a strike—particularly a local one—is not such a hopeless and heart-sickening ordeal as that through which the postmen who went on strike are now so unhappily going. Many will say that these things were surely palpable to the postmen, or ought to have been made known to them, when they talked of striking. We fear that they were not overburdened with good advice at any stage of their proceedings, and it is best to consider these things as they were and are rather than as they should have been.

As the post office system generally is a huge government monopoly, no such resources as are available to the "working man" fall to the lot of the postman or the letter sorter. It is surprising that the Postmen's Union should have lost sight of this tremendous fact—a fact which, we are quite sure, inspired the utterances of the Postmaster-General when he spoke of the danger that extreme action would engender to the men themselves. Hand in hand with the question of general monopoly goes that of the character of the individual. The action of the 400 strikers may officially be held to have affected and even tarnished their characters. Here we realise fully the effect and power of officialism on the individual. Though few will approve of the postmen's strike, we doubt if they will say that these unfortunate men are any the less manly, honest, and honourable than before. Indeed, we feel that the impulse of their hearts outdid the wisdom of their heads, or that their frenzied zeal overcame their discretion. The eulogies passed on those who showed their "devotion" to the department may be considered as of little value. We refer now to the men at the General Post office, of whom the Postmaster-General spoke in terms of almost unqualified praise. These "devoted," heartless creatures had all along acted as decoys to their less sophisticated comrades—they were the enthusiastic men, the street paraders, the hooters and groaners and those most noisy in calling out "Strike! strike!" at their public meetings. The district men, who comprise almost the entire body of strikers, beguiled by such will-o'-the-wisp demonstrations, have now to bear their own sins as well as those of the "devoted" band. The encomiums of the Postmaster-General will not go far to ease the stings of conscience in their loyal hearts; but, possibly, they may have sacrificed even conscience at the altar of "devotion."

For such men few will feel any pity, and it is not too much to say that a large measure of responsibility attaches to their wicked and unmanly conduct.

Taking all these circumstances into consideration, it

is not surprising that great disappointment was expressed on the publication, some weeks ago, of the correspondence between the Postmaster-General and an ex-M.P. on the subject of the re-instatement of the erring and wretched postmen. A few of the younger, the Postmaster-General pointedly said, would be reinstated, subject to certain conditions—and such conditions. The older men were to have no mercy. Their shortcomings, we gather, and those, probably, of the “loyal” section, would be concentrated within themselves, and they would be punished with the utmost severity. This appears worthy of bracketing with the severest samples of Roman law—ancient and effete. Disappointment became greatly accentuated when reports appeared last week of the continuance of what a contemporary called a career of “vengeance,” and the dismissal of merely suspected men—postmen and sorters.

The reinstatement of the whole of the already severely punished men would not be regarded by civilised persons as any sign of weakness and indecision in the administration of the General Post Office. That argument is sometimes applied to savages, but never to any race of intelligent and thoughtful people; therefore the Postmaster-General has no need to apprehend any misunderstanding on that score from futurity. We mention this as it is put forward as a reason for making such a great number of examples. There will be no more strikes in St. Martin's-le-Grand, we feel very sure. The Postmaster's argument is best met by reminding him that each case should be settled on its own merits, and his anxiety with regard to the future may be left to the future. Futurity will look after itself, and will be none the worse for a noble example, and one in accord with philanthropic sentiments many times expressed. The objection that there are no vacancies is one that will not hold water, as we heard months ago from a reliable source that the service is greatly under-manned, both in town and in country.

The Postmaster-General has drawn comparisons between the methods of controlling men in the General Post Office and those generally adopted by employers of labour, but no employer of labour possesses the autocracy of a Postmaster-General. No employer of labour could work the social ruin of 400 men because they had participated in a strike, but, strangely enough, a Government monopoly renders this method of commercial excommunication, with its terrible consequences, comparatively easy of fulfilment. Without going into commercial comparisons which might not altogether redound to the credit of the post office, we can still lay a plea for the exercise of that unstrained mercy which “droppeth as the gentle rain from heaven,” and we trust it will be taken up throughout the country.

There are those connected with the administration of the General Post Office who, judged by their platform orations and their recent careers are inspired by high Christian sentiments towards all ranks and conditions of men. They have advised their hearers again and again to forgive “even unto seventy times seven.” These gentlemen are surely qualified in the fullest degree to urge the Postmaster-General to display largely those grand and divine qualities which go to build up the public and private reputation of a noble-minded English gentleman. No one is more powerful on such subjects than that courtly and soldierly-looking gentleman, the Secretary to the Post Office, and we cannot believe that he would not practice what he has so often and so ably preached. He has now a splendid opportunity of reaping a harvest of heartfelt gratitude.

The Postal Jubilee glory of 1890 will be all the brighter if that “quality of mercy” of which the immortal Bard of Avon has pealed forth such glorious and sublime harmony to the heart and mind, is observed now fully and compassionately to the heart-wrung and sorrow-stricken men who have already received a terrible lesson, and whose thoughtless actions have plunged happy homes and loving wives and relations into an abyss of misery and cruel destitution.

## CORRESPONDENCE.

### Fire Risk Rules.

I have read with great interest your different articles in the REVIEW *re* Fire Insurance Rules, and I can testify as to the arbitrary measures sometimes resorted to, which makes it every day more apparent that one solid and sound rule should be adopted and rigorously kept by all contractors; an illustration follows why this should be so.

A little time ago I made out an estimate and specified for a certain class of cables which would be guaranteed to have an insulation resistance of 600 megohms per mile. Having previously used a large quantity of this said cable, I knew its good quality; nevertheless, after my estimate had been accepted, my client wished that all the materials should be inspected and passed by a certain well-known fire insurance office. Of course, I gladly consented, never dreaming of the amount of trouble and expense this meant. Their inspector said nothing but Silvertown cables would do, and condemned almost everything that was shown.

Now, every man is guided by his own sense, and all these articles had passed on an installation not insured by the said office, and received a splendid report.

My complaint is this: after a contractor has given a price, not necessarily a low one, and then finds that the fire office requires material so much higher in price, the only thing he can do is to go to his client and tell him or her the price will be so much more than you expected, owing to this interference; in nine cases out of ten they would think otherwise, and throw over the whole thing, saying you give a price and cannot keep it. My question is, Why?

A. J. Howes.

September 15th, 1890.

### Elmore Copper Company.

I should esteem it a great favour if you would kindly answer the following enquiries in your next issue. Do you know anything about the commercial value of Elmore's process for manufacturing tubes, wires, &c.? Is the company doing any business, and are their articles likely to be adopted and the business to be a success?

Thanking you in advance for any information, I enclose my card and remain

A Young Electrician.

September 12th, 1890.

[The process seems to be a valuable one for tubes, cylinders, &c., but we see no advantage over other unpatentable processes for producing high conductivity wire. It is impossible to say what the company is doing other than putting down plant and floating sub-companies, the business should be a success, but is probably much over-capitalised.—EDS. ELEC. REV.]

### Permanent Magnets.

The article published in your last issue on above subject involves considerable misapprehension. I beg to submit a few facts on this matter.

The so-called French steels of Clemandot and Marchal are methods of treating magnet steel of any make. M. Clemandot's is by great compression and subsequent magnetising, without any hardening. Under this process, my steel and others gives similar results.

Marchal is a small but skilful magnet maker, who is using English steel supplied by the successor in my French business. This gentleman is now in Sheffield, and tells me he has his own system, both as to the solution employed and the means of regulating the

heat of the steel. He also considers Clemandot's process worthless.

The only French steel I have found employed in instrument work at Paris is that known as "Alevard," which firm also supply finished magnets.

About ten years since I introduced my quality in France, and found no difficulty in competing with the Alevard, as mine was both more easily worked and more powerful magnetically. The same authority informs me that, after M. Charrier's decease, the Alevard mark has been irregular, and though sometimes as good as any, is also at times inferior.

I supplied several of the principal consumers at Paris for years, and since ceding my trade there the same customers have continued to use English steel from my successor.

There are several magnet steels made here now, which give passable results, but a great deal depends on the manipulation of the steel, viz., obtaining the best heat and controlling it, unless the heated magnets are brought in contact with the water at exactly the same temperature there will be great variation in the induction. A recent case occurred where  $2\frac{1}{4}$  times the induction was obtained when the steel was treated in a better way, and from this cause delicate experiments such as those detailed in the article may be largely invalidated.

As scientific men are supposed not to know much about magnetism, it can scarcely be expected that mere steel makers should either. It is surely the province of electricians and chemists to tell us what is wanted, and then it will be our function to produce it.

We have no means of conducting delicate electromagnetic experiments, but must look at it as a matter of the compositions of the material. We employ certain constituents which have been varied in proportion, and have had considerable expense in analyses and test magnets, with the result that what one consumer says is excellent another reports worthless; for instance, one of the marks comes out badly in the experiments of the article, which my friend from Paris says is excellent steel, if properly handled, and that Marchal would make it come out first class. If electricians are not satisfied with the magnet steels as now supplied, let them formulate the composition of a perfect material for the purpose, so that we may know what to produce.

There is nothing said in the article as to the chemistry of the steels; but that is the manufacturer's point of view.

As to English magnet steel having deteriorated, there is, practically, only one French magnet steel, which is certainly not superior, if equal, to several produced here.

I may add that good magnet steels are produced in Styria and Germany; but as those are not alluded to in the article, need not be further noticed.

#### An Answer of Thanks.

Many thanks for your leading article on my labours. You have declared your adhesion to the main point—"that there is only one kind of electricity." For this adhesion to my theory of electricity I have sincerely to thank you, but in doing so, you must excuse me for doing my duty toward another party. By God's kind hand I had a pious mother, who taught me from my earliest days to put my trust in God and His promises, one of which is, "Commit thy works unto the Lord and thy thoughts shall be established" (Prov. xvi., 3); another is, "Trust in the Lord with all thine heart and lean not unto thine own understanding; In all thy ways acknowledge Him and He will direct thy paths" (Prov. iii., 5). I trusted in these promises and God has graciously fulfilled them in my case. He has made you the instrument of giving me the opportunity of thanking Him publicly for the gracious fulfilment of His promise. In making this public declaration of

religious principle in your columns, I am well aware that by doing so I will arouse a spirit of opposition in the minds of some who will assert that your journal is devoted to the promotion of science and not religion. I would therefore shut their mouths by pointing out that we now live in very exceptional times. In my young days no journal devoted to politics and secular matters would admit into its columns religious subjects, but now all this is changed; the secular press is now full of articles bearing on religious subjects, so much so, that some have asserted "that the press has taken the place of the pulpit;" but alas, the great body of the semi-religious articles in the secular press are against true religion, and either openly or disguisedly favour superstition in one form or another. Now the main object of your journal is the promotion of the science of electricity, and one of the forms in which we see electricity is that of light. Now, concerning the origin of light, we have the clearest possible statement in the Bible: "God said 'Let there be light, and there was light'" (Gen. i., 3). Herein we have the positive information that light and consequently electricity came into existence instantaneously; they were created by the command of God. It is a distinct intimation that they did not come by the God-defying dogma of *evolution*. This is a grand subject. I hope all the electricians who read this will in the future, by their words and writings, keep unsullied this God-given foundation of the science of electricity. I now turn to the secular part of the subject, as you have given your adhesion to the main point, "*that there is only one kind of electricity*," and consequently that there is no foundation in fact for Faraday's assertion that there are two electricities or powers. I defer, for the present, noticing your remarks wherein you differ from me concerning the results of some of my experiments, as I am at present preparing to make some new experiments which I have reason to believe will throw still more light on the subject.

James Johnstone.

#### The Electric Light at Bath.

In your issue of September 5th, I noticed in the form of a leaderette, extracts from a letter written by Charles Powell, who I conclude imposed upon you by stating that he "recently had a run down to Bath," and that he "met the police going to the station to report lamps out and went in with them," &c. These statements are utterly untrue, as this person, instead of being the impartial looker-on that he would have you suppose, was actually in my employ at the time he professes to have visited the Bath Central Station, and working in the engine-room as driver of one of the engines, and was summarily discharged by me for savagely assaulting the second engineer, who had upbraided him for his negligence, which resulted in a breakdown and temporary extinguishment of the lights. Your contemporaries, the *Electrician* and the *Electrical Engineer*, have been imposed upon by the same person and published similar information, but, unlike yourselves, the *Electrician* had the fairness to give the name of their informant, and, had it not been for their very properly doing this, I should have been unable to expose the low cunning of this man, who when leaving here intimated to my staff that he would have his revenge for being dismissed, hence his communications to the technical press. I regret that you should have published as apparently facts, the statements of a discharged employé who appears to be as unscrupulous as he is vindictive.

H. S. Massingham.

September 16th, 1890.

[We are pleased to insert Mr. Massingham's letter, but his ideas of fairness are peculiar. It is not generally considered etiquette in journalism to give the names of those who supply information, and there was nothing to show that the news sent to us was in any way erroneous.—EDS. ELEC. REV.]

RAILWAY ACCIDENTS FOR THE YEAR 1889.

THE Board of Trade Report on the above subject for the past year shows the total number killed in the working of railways to have been 1,076, and the number injured, 4,836. Of these 183 persons killed and 1,829 persons injured were passengers, but only 88 were killed and 1,076 injured in consequence of accidents to, or collisions between, trains. The deaths of the remaining 95 passengers, and the injuries to 813, were due to a variety of other causes, and especially to want of caution on the part of the individuals themselves.

The casualties for the year have been greatly heightened by the Armagh accident, which, it will be remembered, resulted in the death of 80 and injury to 262 children and others. Deducting this 80 killed, we have a result of 8 passengers who lost their lives from causes beyond their own control during the period, as compared with 11 for the previous year, and 25 for 1887. Making a like reduction with respect to the injured, the result is not, however, so favourable, for it leaves us with a comparison of 744 injured for 1889, as against 594 for 1888, and 538 for 1887. One is naturally inclined to make exceptions of heavy casualties such as the Armagh collision, the Tay Bridge disaster, &c., although, in point of fact, it is not quite a logical way of handling the results dealt with and considered year by year. Casting aside the exception, and looking simply at the year's result, we find that although there has been an increase of passenger journeys over those of 1888 to the extent of 2,683,909, the proportion of killed and injured to the number carried, exclusive in either case of season ticket holders, is brought down to figures very closely approximating to those of the Tay Bridge year. The result, on the whole, is not congratulatory, and we can only express a hope that future returns may not be marred by more of those heavy disasters, which cause a thrill to pass through the nation, for some years to come.

In reviewing the report, we have chiefly to deal with

those portions wherein electrical apparatus plays a part, or where, had it been in use, it might have proved of service in averting disaster.

Collisions between engines and trains following one another on the same line of rails, excepting at junctions, stations, or sidings, have, during the year, been productive of but one case, resulting in injury to 13 passengers and 1 servant. This was due to a signalman omitting to signal for permission to admit a passenger train into a section in which was standing another train at the time. A heavy fog prevailed, but that in no way authorised the signalman sending the train into the section against the electrical signals. In this case, had the outdoor signals been interlocked with the electrical signals, the probability is that the train would have been held at the stop signal, and the collision avoided.

Collisions at junctions amount to four. 88 passengers and 6 servants were injured. The most serious of these was that on the Lancashire and Yorkshire, on the 7th December; and that on the London, Chatham and Dover, on the 14th November. All of these accidents are said to be the result of want of care or judgment on the part of drivers or signalmen, and it would appear that the only way of avoiding them is to insist upon the preservation of a given space between all moving trains, or by making it obligatory upon every driver to bring his train to a dead stop before entering a junction. With the heavy traffic which now has to be dealt with at many important junctions, and the necessity of bringing forward trains for connection as readily as possible, we quite see and appreciate the difficulties which beset the question; but still, we feel that improvements are yet to be made, probably by extending the distance of distant signals, so as to give earlier intimation to drivers when they are required to stop.

Collisions within fixed signals at stations or sidings resulted in enquiries into 25 cases, in which seven passengers and one servant were killed, and 143 passengers and 20 servants injured. Nine of these were

mainly due to mistakes in block working, arising from forgetfulness or want of care, three to mistakes of pointsmen, 11 mainly to want of care of engine drivers, one to foggy weather, two to want of proper interlocking, two to want of brake power, and two to want of block working.

The want of block apparatus will, no doubt, now be supplied—if not under the recommendation of the inspecting officer, it will under the recent powers conferred upon the Board of Trade.

There were two collisions between engines and trains meeting from opposite directions, by which 24 passengers were injured. One was due to the engine driver running against the signal, and the other to the mistake of a signal porter.

The foregoing are the main points which affect, or are affected, by the electrical branch of the railway service. The time has now come when the employment of a block system, together with that of an interlocking system for points and signals is about to be enforced. In a short time all passenger lines will be thus equipped. It is not many years since pioneers were fighting for the introduction of either. Slowly the antipathies of the old school have been worn away; in many instances by arguments of so forcible a character as to no longer admit of obstruction. To the larger, more important, and more experienced companies of England and Scotland, the demands of the Board of Trade under their recent powers means, perhaps, little more than a confirmation of what they have done—as showing they were wise in, of their own will, doing that which, had they left it undone, must now have been performed under the orders of an Act of Parliament. Yet we cannot help thinking—indeed, it is not a question of doubt with us at all—that what is now being done is, although a very important part, still only a part of what has to be done to render railway working more secure. It has been our province more than once to point out that railway train working is dependent upon a double action—first, that of the electric signals, and then that of the line signals. The driver is governed by the latter. The signalman who works them is governed by the electrical signals. With but few exceptions, the one is completely dissociated from the other. The devices adopted are made as evident as possible, but still they have to be interpreted. The signalman has to obtain the electric signal, and to convey it by his mechanical signals to the engine driver.

It is quite possible to lock the one with the other. It has been done, and is in daily use. It would probably have been too great a revolution to have asked for its application to all block signals; but as there can be no question of its great advantage, it is to be somewhat regretted that an extended use of it has not been advocated, especially upon busy parts of the various systems. Doubtless the time will come for its adoption. Although originally greatly opposed, the block has now become as much a part and portion of our railway system as the rails upon which the traffic is carried. We feel that it cannot be a great while before the propriety of coupling together those two important

adjuncts which now form the controlling agent for the regulation of the traffic makes itself as apparent and as necessary to the management of the different important companies as did the earlier adoption of the block. Where this is done, we shall look for a considerable reduction in railway casualties.

#### Heating of Dynamos.

M. RECHNIEWSKI, in a paper read before the International Society of Electricians, deals with the heating of dynamos, and thinks that the "maximum temperature which can safely be admitted for the armature is about 70°, say about 40° to 50° above the temperature of the surrounding air. At this point insulating material stands well, and the effect of increased resistance of the copper is little noticeable." We are dealing with the same subject on another page, and it will be observed that, as regards the maximum temperature permissible, M. Rechniewski's views and our own practically coincide.

#### Output of Dynamos.

IN proceeding to consider the output M. Rechniewski points out that the rise of temperature due to hysteresis is similar in machines in which the armatures have the same peripheral velocity, provided all the linear dimensions are proportionally increased or diminished. He concludes that a machine having its linear dimensions increased  $n$  times, will give an output  $n^3$  times that of the smaller one if it is to attain in continuous running the same temperature. The means of eliminating Foucault currents, fully described in "A Synthetic Study of Dynamo Machines" some time since, also come in for a share of the author's attention.

#### Electric Tramways and Telephones.

THE general feeling with reference to the fight between the electric tramway and the telephone companies, as to which party is to arrange matters so that the telephone circuits are to remain undisturbed by possible leakage from the electric tramways is, that the telephone companies must give way. These companies practically claim, as first comers, the sole use of the earth, and argue that the disturbance to which their circuits are liable from strong currents should be obviated by the tramway companies insulating their lines in such a way that there should be no leakage. In a recent decision by Chancellor Gibson, with reference to a dispute in Knoxville, America, the Chancellor argued that, "If the contention that no company using a strong current, can lawfully use the earth for a return current without the telephone company's leave, be correct, then no electric company can ever use the underground on which Knoxville is built without the consent of the telephone company. It makes no difference what grand discoveries and inventions in the use of electricity may be made. Coal, wood, gas, steam and animal power may all be superseded by electrical devices, machines may be invented to heat and light all of our homes, do all of our cooking, propel all of our vehicles and machinery, and all or a large part of this electricity may be drawn from the earth, or it may be drawn from the air, and yet Knoxville and her

people are to be denied all of these wonderful benefits for all the ages to come, if they, either through the earth or through the air, in any way cripple or injure the feeble current of the telephone company, unless the telephone company gives or sells its consent."

#### The Right of Monopoly.

PROVIDED there were no means of curing the evil effects of the tramway currents, the contention of the telephone company would appear a good one, as the value of their system to the citizens may be just as great as that of an electric tramway, and, under such circumstances, the Chancellor's remarks would be hardly to the point. Again, the question may be, whether a monopoly was really granted to the company, it being unforeseen at the time that any other industry would spring up that would interfere with the existing system of telephones; if the monopoly were granted, then no matter how hardly it may press upon new comers this monopoly can hardly be repudiated without breach of contract, and though it should not be allowed to stay all further progress, it ought to be recognised by some compensation being given. The mere fact that it would cost the tramway company more than the telephone company to cure the evil is hardly a conclusive argument for forcing the telephone company to give way, though no doubt the latter is carrying out a dog-in-the-manger policy by taking up the course it is.

#### Duplication of Telephone Wires.

THE argument that all the telephone companies have to do is to duplicate their wires may appear a very plain one, and it would be so if local working only were the order of the day; but when the working has to be over trunk lines on to other systems, it either means duplicating the trunk lines and the circuits of the other systems also, or else working with induction coil repeaters at the ends of the trunk, which is not conducive to good speaking.

#### The Post Office and Electrical Disturbances.

AS regards electric light circuits, considerable trouble, we believe, has been experienced by the Postal Authorities from the action of the Ferranti mains of the London Electric Supply Corporation. In the event of this disturbance not being cured by the Corporation, is it to call upon the Department to duplicate their wires?

#### The Efficiency of Arc Lamps.

WE should have thought the time had gone by for electrical journals to describe any particular arc lamp as giving more light per horse-power than another. Yet we find an esteemed American contemporary seriously assuring its readers that, with respect to one design of lamp, such is said to be the case. As a matter of fact, for the same current and difference of potentials there is produced with similar carbons the same amount of light; and while makers may endeavour to delude the public in the manner referred to, technical journals ought to be careful that they do not appear to lend themselves to the deception. Regarding the makers, we never knew one yet who did not claim that his lamp, as compared with others, took least power and gave the steadiest light.

#### Mitis Metal for Field Magnets.

PROFESSOR SILVANUS THOMPSON'S Cantor lectures on "The Electro-magnet" teem with practical hints. Speaking of Mitis metal, which is a kind of cast wrought iron rendered fluid by the addition of a small percentage of aluminium, Dr. Thompson states that he has found this metal far superior to ordinary cast iron, and not much inferior to wrought iron. It is well known that the field magnets of dynamos and motors are made to certain forms, mainly to avoid expensive forgings on the one hand, or inferior results with cast iron on the other. In most cases a compromise is made by using good wrought iron for the straight cores, and cast iron for the pole pieces, the latter involving difficult work if forged out of wrought iron. Mitis metal it appears, if easily produced, would bring about material deviations from existing types of field magnets, especially for the cheaper class of dynamos and motors. Indeed, a reasonably small difference in permeability may be compensated for by some advantageous design which could not hitherto be adopted in the case of wrought iron, owing to structural difficulties. Further research in this direction might lead to important results from a commercial point of view.

#### Electric Traction.

IT is anticipated that Electric Traction will form an important topic of discussion during the forthcoming meetings of the several American Street Railway Associations. Until three years ago these societies not only occupied themselves exclusively with matters concerning horses, stables, manure and horse cars, but when the subject of electric haulage was mooted the introducers of the novel "fad" were looked upon with suspicion and scepticism. Times have changed with astonishing rapidity. Many of the advocates of the horse have been converted to modern ideas, others have dropped avowed opposition and are now watching events. None can upset the remarkable fact that out of 8,652 miles of tramways in the United States, 1,753 miles, or nearly 20 per cent., are now worked with electric cars. We expect, therefore, to hear of many practical results from practical men who view the present situation entirely from the financial point of view: thus we may contrast the utterances of the old-fashioned tramway man with those of the modern electrical engineer, and draw useful conclusions.

#### Fatal Electric Tram Accident.

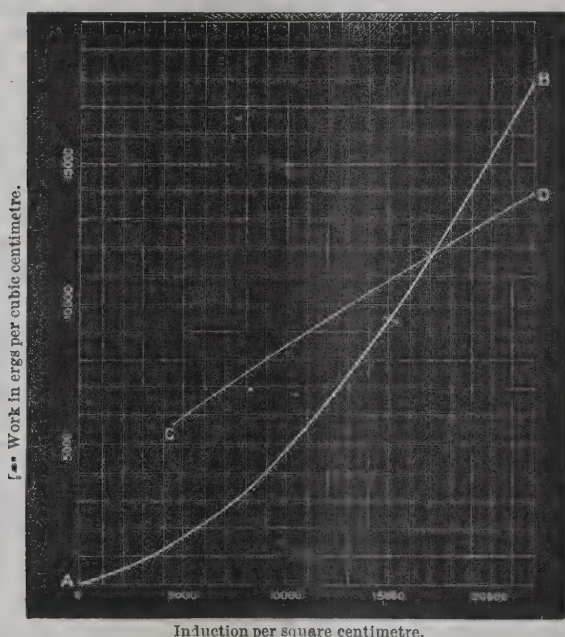

A TELEGRAM from Florence under the date of September 23rd, announces that a fatal accident occurred on the electric tramway between that city and Fiesole. The cars ran off the track, five persons being killed on the spot and 20 others injured. On being informed of the occurrence, the King and Queen and the Prince of Naples at once gave up the idea of attending the races, as had been their intention, and visited the injured. Such a fatality reflects seriously upon the tramway authorities, and there must have been either inefficient driving, badly constructed permanent way, or failure of brakes, in all of which cases the blame will be attached to the electric system by the timid public. This is all the more to be regretted since electric traction has been in a fair way of gaining public favour in Italy.

A SYNTHETIC STUDY OF DYNAMO  
MACHINES.

(Continued from page 207.)

IX.—THE HEATING OF MACHINES (*continued*).

As stated in our last article, the temperature attained by the best class of machines, when working in the normal atmosphere for which they are designed, seldom exceeds 75° C. On land it is generally under this, and the rise of temperature allowed from the start is most frequently from 30° to 40° C., which is, of course, included in the 75° C. mentioned above, or whatever may be the maximum attained. The evil of overheating is not perceived at once, or it may be for a long time after a machine has been set to work. The deterioration of the insulating material is gradual, and consists in its eventually "perishing" or becoming "rotten" with the continuous heatings to which it is subjected. When this condition is reached, it has lost all its original tenacity and toughness, and has become extremely brittle. The paper, calico or fibre has become of a dark colour, and the cotton covering of the wire has a semi-charred appearance. Although the insulation resistance may be as high or higher, in fact, than it was originally, the armature is more liable to break down when in this state. It is, therefore, of the greatest importance to prevent overheating, if it is desired to combine long life with high efficiency.

Induction per square centimetre.

FIG. 150.

We have said that there are three sources of waste—first, the energy spent in the conductors due to their having some resistance; secondly, the energy expended in continually changing the direction of the magnetism in the rotating core; and, thirdly, the energy of feeble parasitic currents generated in both conductors and core. The energy dissipated in the armature due to the first cause can be calculated from the resistance of the winding from brush to brush and the total current flowing. The loss from the third cause cannot be very readily calculated, but may be rendered almost negligible by adopting the precautions insisted on in Section VII., dealing with parasitic currents. The points necessary to be observed in construction, so that these might be eliminated as much as possible, were then clearly stated; briefly, the core has to be supported so that no part of the supports is subject to inductive action, the core has to be laminated in planes perpendicular to the direction of induction, and parallel to the direction of motion, and the conductors have to be divided and grouped in certain ways in the winding. If these rules are carefully attended to, the loss due to parasitic currents be-

comes unimportant; not so, however, is the second source of loss, which we are about to consider.

In carrying a piece of iron through a cycle of magnetisation, there is expended in the operation a definite amount of energy depending on the induction and on the character of the iron. Starting with a piece of iron magnetised in one direction, a cycle defines the operation by which the induction is reduced to zero, reversed and brought up to the same strength in the opposite direction, again reduced to zero, and finally brought up to its first degree of induction. Imagining for a moment that every molecule of iron is a small magnet, it will be readily perceived that, since the axial direction of the molecules is governed by the direction of induction, in one complete cycle each molecule must rotate once with reference to the mass of which it forms a unit. In producing this rotation involved by the magnetic cycle, work is performed either in overcoming a kind of frictional resistance, as has been hitherto assumed, or in overcoming the magnetic forces which the molecular magnets exert upon each other, as has been suggested recently by Prof. Ewing. The energy expended in carrying annealed soft iron wire through cycles such as described, has been carefully determined by this experimenter, a curve showing the results being given in fig. 150. The induction per square centimetre is plotted as abscissæ, and the energy in ergs required to carry a cubic centimetre of soft iron through a complete cycle at different inductions is measured by ordinates. The resulting curve, A, B, shows that the energy increases at a somewhat greater rate than the induction. The use of the curve, C, D, will be seen hereafter.

In applying these results to the case of a revolving armature core, it has been assumed that, in causing the molecules to rotate, there is performed the same amount of work as given above, although in the former case the molecular rotation is caused by varying the intensity of magnetisation, carrying it through zero and reversing its direction, while, in the case of the armature, it is produced by change in direction without change in intensity. The assumption seems a fair one, though it must be remembered that the energy required is reduced somewhat in the presence of vibration, and that consequently the work, in a moving armature core, might be expected to be under the amount here given. Again, Ewing's experiments were performed by making the changes very slowly, and, in dealing with armatures, the farther assumption has to be made that the work done per cycle is the same, whether the changes are slow or rapid. Some idea of the power wasted in reversing the magnetism of the armature may now be obtained. Taking a direct current two-pole 300-light machine having a ring core, say, of 33 centimetres diameter, with an internal opening of 23 centimetres and a length of 28 centimetres, the same amount of soft iron contained in such a core is, allowing for insulation between the plates, 11,000 cubic centimetres. The induction is, say, 17,000, and from the curve we get the ergs expended per cycle per cubic centimetre as 11,800. The speed of the armature being

900 revolutions per minute, this gives us  $11,000 \times \frac{900}{60}$

$\times 11,800$  ergs per second = 195 watts. There would probably be expended in heating the armature coils of such a machine 780 watts, the heat generated in magnetising and demagnetising the iron core constituting, therefore, about 20 per cent. of the total heat generated in the armature. In alternating current machines, where the number of cycles per second is rather more than six times as many, it will be seen that the work expended on changing the direction of the magnetism becomes of great importance relatively to the other sources of waste.

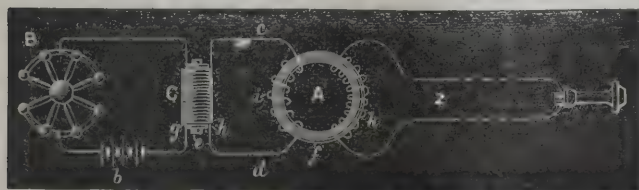

In this article, we have seen that the amount of heat generated in the armature can be calculated with a fair degree of accuracy. In our next article, we have to determine the amount of cooling surface it is necessary to allow in order that the heat generated may be got rid of without exceeding the specified limit of temperature.

(To be continued.)

## TELEPHONE INDUCTION COILS.

In a recent number of the *Electrical Engineer* (New York), a system of telephony devised by Mr. T. D. Lockwood is described. The employment of closed circuit induction coils in telephony involves certain considerations which do not appear at first sight. It is, of course, comparatively easy to operate electric light transformers by means of reversals of the primary current, because, since the secondary currents to be evolved need have no special form, character, or quality, these reversals may readily be produced by using an alternating dynamo as a source and by sending its currents unrectified through the primary helix. But no such procedure is possible in telephony, for the voice currents developed in the secondary circuit of the induction coil, which are to traverse the line and reproduce speech at the distant station, must, so to speak, be an electrical copy of the variations of the sound waves initiating them, and also of the sound waves they are to reproduce. Up to the present time, however, it has not been found practicable to produce reversals in the primary circuit of transmitting telephone induction coils, and in all such instruments which have gone into use the change which the operation of the transmitter effects in the primary circuit is not a reversal of current, and hence cannot result in a reversal of magnetism with its inherently-consequent zero moment. It is not even a succession of absolute cessations and emissions of current, as in the make and break of the Ruhmkorff induction coils. The change which is effected by such operation is the variation of current strength, tending to produce a variation of magnetic intensity in the core, which, if produced, results in corresponding magneto-electric currents in the secondary helix and line; but the magnetism of an iron ring core once magnetised does not greatly vary when simple changes only are made in the strength of the magnetising current. Thus, while it tends to advantage to employ induction coils having closed magnetic circuit cores, such a procedure demands also a practical method of producing reversals in the primary circuit of the induction coil, and it is to accomplish the latter object that Mr. Lockwood has designed the system we are about to describe.

The method employed is illustrated diagrammatically in the fig. Here B is a multiple-contact microphone, which is placed in the circuit of a battery, *b*, in which also is serially included the primary conductor, *g*, of the induction coil, C. This circuit may be termed the "local circuit." The secondary conductor, *h*, of this coil has the same number of convolutions, and is of the same size wire, and both are, as usual, wound upon a cylindrical core, *e*, of iron wires.

The induction coil, A, has a continuous core, *f*, of soft iron, and constituting a closed magnetic circuit. This has a primary conductor, *i*, the same size and length as that employed in the two helices of the first coil, which is joined up in circuit with the secondary conductor, *h*, of induction coil, C, and the closed circuit so constituted may be termed the "intermediate circuit." Thus alternating currents generated in conductor, *h*, inductively by changes of current in conductor, *g*, will be of like character with such changes, and will of necessity circulate in and through the primary conductor, *i*, of induction coil, A. The resistance of the conductors, *g* and *h* and *i*, is low, being but a fraction of an ohm.

The secondary conductor, *k*, of coil A, is of fine wire, for the purpose of securing a great many convolutions, it being required not only to transfer electrical energy from the reversals circulating in *i* to the secondary con-

ductor, *k*, but to raise the potential. The secondary, *k*, of the induction coil, A, is connected with the wires of the main telephone circuit, Z, leading to the distant station and telephone receiver. In actual practice Mr. Lockwood winds the primary coil in alternate sections, spaces being left between each for similar sections of the secondary winding. The advantage of this method of winding is that the magnetisation is thereby distributed uniformly, and is enabled to act equally upon all parts of the core.

It will be observed that the function of the first induction coil is to develop alternating currents in the intermediate circuit without raising the potential of such currents. If the potential in this circuit were to be raised, it would be necessary to multiply the convolutions of both the helices included in it, with a consequent increase in cost, in resistance, and in waste of energy. Furthermore, it is of great importance to keep down the resistance of this intermediate circuit, for the reason that in telephony self-induction is a potent factor in opposing the proper operation of the current, and the self-induction of any circuit of which coils or helices form a part is mainly dependent upon the number of their convolutions. Hence, there is special utility in employing a few convolutions of thick wire instead of a greater number of convolutions of thinner wire in the intermediate circuit.

We witnessed some experiments a few years ago with coils constructed like transformers, to be used for translation purposes from a single wire to a double wire system, but the *speaking* results were extremely poor, though the ringing of the call bells (on the magneto principle) was all that could be desired. On the other hand, it was found that when ordinary induction coils were used as translators, the speaking was excellent, but the magneto bells would not ring. Mr. Lockwood's method seems well adapted to make both speaking and ringing good, but the use of two induction coils would appear likely to involve a loss of power, and it seems open to doubt whether any directly beneficial result is practically found to result from the new arrangement. We observe that the *Electrical Engineer* is silent with reference to the practical working of this method.

BRITISH ASSOCIATION FOR THE ADVANCE-  
MENT OF SCIENCE.—LEEDS, 1890.

## ON THE SPECIFIC RESISTANCE OF COPPER.

By T. C. FITZPATRICK.

(Read in Section A, September 9th, 1890, in conjunction with the report of the Committee on Electrical Standards.)

ALL the values given in tables for the specific resistance of the metals are directly or indirectly obtained from the values given by Matthiessen in his series of papers published in the "Transactions of the Royal Society" for the years 1860—1864, and in the reports of the British Association for the same years.

In the "Transactions" for the year 1860 is a paper by Matthiessen on the conductivity of pure copper and on the effects of impurities. No alloy of copper has as high a conductivity as the pure metal. His results are expressed in terms of the conductivity of a hard-drawn silver wire (100 at 0°). He gives the following values for samples of copper carefully prepared by himself:—

(1)	93.00	at 18.6°	} Giving a mean value of 93.08 at 18.9° as the conductivity of pure copper.
(2)	93.46	" 20.2°	
(3)	93.02	" 18.4°	
(4)	92.76	" 19.3°	
(5)	92.99	" 17.5°	

Numbers are given showing the effect on the conductivity of small quantities of oxide, and he states that he found it necessary to pass hydrogen through the molten metal for some time for entire reduction. In the "Transactions" for 1862 Dr. Matthiessen has a paper on the influence of temperature on the conductivity of metals. He again expresses his results in terms of a hard-drawn silver wire.

On page 8 will be found the results of his experiments on copper: the lowest temperature at which measurements were made was 12° or 16°; he there shows how the results for pure copper measured at 18° may be reduced to 0° C.; but no measurement was actually made at 0° for any of the metals experimented with.

\* "Phil. Trans.," 1860, p. 85.

He expresses the influence of temperature on a hard-drawn copper wire; the mean result of a number of determinations by the equation

$$\lambda = 100 - .38701 t + .0009009 t^2$$

where 100 is the conductivity of copper at 0° C., so that a hard-drawn silver and copper wire have the same conductivity at 0° C.

The values obtained by comparison with a hard-drawn silver wire are then largely the source of the tables of specific resistances; but at the end of his appendix to the report of the Electrical Standards Committee for 1864, Matthiessen gives values for hard-drawn silver and copper wires in terms of the new B.A. unit; expressed as the resistance of a wire one metre long, weighing one gramme.

These values are:—

Copper	...	...	.1469
Silver	...	...	.1682

The same table of values is given in the *Philosophical Magazine* for 1865, where also is given a table of specific resistances for wires 1 metre long and 1 millimetre diameter expressed in terms of the B.A. units, calculated from the value of the known conducting power of the gold-silver alloy in terms of hard-drawn silver, and also in terms of the B.A. unit.

The values thus obtained do not agree at all well with the results calculated for the resistances of the gramme metre by the specific gravities of the elements furnished by tables.

Thus—

Silver	...	...	.02048	...	.02603
Copper	...	...	.02090	...	.02104

He states that he omitted to determine the specific gravity of the copper used in his experiments; he probably would not have obtained any very adequate results, and the weight of copper he used varied from 1.5 to 4 grammes.

The accuracy of Matthiessen's results seems to depend, therefore, on the accuracy of his determination of the resistance in terms of the B.A. unit of a hard-drawn silver wire; in considering, therefore, the question of the preparation of samples of copper of higher conductivities than Matthiessen obtained, it may be suggested that the cause of the difference is not explained by the fact that Matthiessen did not prepare pure copper, but by the error in the value of the standard with which the comparison was made.

I have, therefore, made a series of experiments on the resistance of pure silver wires; and, as a general result, have obtained a value identical with that of Matthiessen; the difference is not due, therefore, to an error in the standard employed, as far as my experiments go.

Matthiessen does not give anywhere the details of his measurements of the specific resistances of the metals in terms of the B.A. unit; in the B.A. report he simply mentions that an approximate table is subjoined, not even stating the fact that the values are for a temperature of 0° C. I conclude, therefore, that these values are calculated out from the former, of which an account is given in the same B.A. report, and which were performed at a temperature of 20° C.

I have, therefore, on this account, as well as for other reasons stated later, made my measurements at the temperature of the air, and believe that as his values were reduced by a temperature coefficient to values at 0° C.; I shall, by using the same temperature coefficient, and raising his value to near that for 20° C., obtain results directly comparable with Matthiessen's direct measurements.

For the measurement of the resistance of the specimens of wire a Wheatstone's bridge arrangement was employed, two of the arms of the bridge were formed by a 10 and 1 standard B.A. unit, namely (66 and g); these were so nearly 10 to 1, that they were taken to be in that ratio.

The third arm was one-third of a B.A. unit, and in the fourth arm was the wire to be measured, this was stretched on a flat board, and soldered at the ends to copper plates, to which connecting wires were also soldered; the length of wire used was generally a little less than two metres, and the wires were, approximately, No. 18 B.W.G. The board had scales screwed to it at the two ends; the board and wire were placed in a long bath made of zinc, and filled with paraffin; wires which were left in the bath for some days, and, in more than one case, several weeks, were not found to have been at all acted on by the oil.

One end of the wire, P<sub>2</sub>, Q<sub>2</sub>, was connected by a binding screw through an adjustable resistance, r, (½ metre of copper wire) to the mercury cup, Q<sub>1</sub>, in which was one of the legs of the one-third coil, and also to a reversing key in the battery circuit.

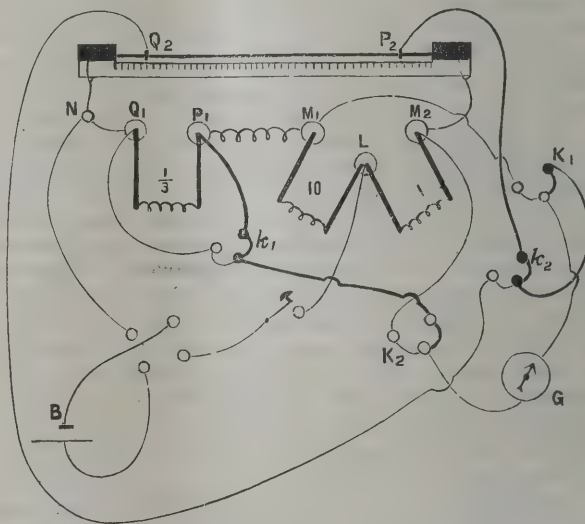

The ⅓rd and the 10 were connected up together through an adjustable resistance, P<sub>1</sub>, M<sub>1</sub>, one leg of each of the coils 10 and 1 were in the same mercury cup, L; and the other end of the 1 B.A. unit was connected with the other end of the wire, P<sub>3</sub>, Q<sub>3</sub>.

A single Leclanché cell was connected up with the reversing key and the fourth point of this key was connected with the mercury cup, L, into which the legs of 10 and 1 dipped. In this circuit there was also a touch key. The galvanometer circuit was always made, and thus there was no thermo-electric effect on meeting the galvanometer circuit. To each of the mercury cups, Q<sub>1</sub>, P<sub>1</sub>, M<sub>1</sub>, M<sub>2</sub>, were connected with separate binding screws two thick wires, one of which was welded to the copper plate at the bottom of the mercury cup. Each of these latter wires were connected with two way-keys; those in P<sub>1</sub> and Q<sub>1</sub>, to the key, k<sub>1</sub>; those in M<sub>1</sub> to the key, K<sub>1</sub>; those in M<sub>2</sub> to the key, K<sub>2</sub>.

The base points of the keys, K<sub>1</sub> and K<sub>2</sub>, were connected with a delicate reflecting galvanometer, that employed for the com-

parison of the standards on the Fleming bridge. The base of the key, k<sub>1</sub>, was connected with the third point on the key K<sub>2</sub>, and the third point, on the key, K<sub>1</sub>, was connected to the base point of a fourth key, k<sub>2</sub>, the two other points on this key being connected with riders, with which contact can be made with two points on the wire, P<sub>2</sub>, Q<sub>2</sub>; the riders had straight edges, and thus their positions on the scales could be easily determined. In performing an experiment, the keys, K<sub>1</sub> and K<sub>2</sub>, were so connected that the mercury cups, and so the ends of the coils, 10 and 1, were in circuit with the galvanometer. The resistance, R, P<sub>1</sub>, M<sub>1</sub>, was then varied till, on making the battery circuit, no deflection resulted. The ends of the 10 and 1 were then at the same potential, and as the other ends of these coils were connected with the same pole of the battery, there was the same fall of potential on the two lines.

The keys, K<sub>1</sub> and K<sub>2</sub>, were then reversed, and by the keys, k<sub>1</sub> and k<sub>2</sub>, one end of ⅓rd coil and one point on the wire, P<sub>2</sub>, Q<sub>2</sub>, were connected through the galvanometer, and afterwards the two other ends. The riders were adjusted till there was no deflection of the galvanometer. The length of wire between the two riders had a resistance of ⅓th that of the ⅓rd B.A. unit coil.

By means of the series of keys it was easy to repeat the observations and to connect the ends of ⅓rd coil with the wire. The resistance, R, did not often change during the experiments, as the room was at a constant temperature, any change in R only caused a shifting of the position of the riders. In each experiment, after all the adjustments, the bath was well stirred and everything left for half-an-hour. It was generally found that the riders did not require any adjustment. The battery was reversed and all the coils moved. The latter never caused any effect; sometimes the reversal of the battery caused a shifting of the two riders a millimetre or two in the same direction.

Another reading was taken three or four hours after. The coils ⅓rd, 10, and 1, were in water baths, and their temperature remained the same for hours together. The temperature of the paraffin bath, of course, was not so constant, it was kept well stirred in, and a thermometer reading to .2° C. never showed any difference in the temperature at the different ends of the bath when the readings were taken. The thermometer employed was Kew corrected; and the corrections given were verified by recent comparison with a platinum thermometer by Mr. Griffiths.

Since the two standard coils employed were accurately in the ratio of 10 to 1, the accuracy of the resistance measurement depended entirely on the value of the ⅓ B.A. unit. This was first made as nearly as possible ⅓, but it was found that for the size of the wires measured (18 B.W.G.) this was too high a resistance, it had, therefore, to be reduced. For the determination of its value there was cut out in a block of paraffin wax a large central mercury cup and outside this a circular channel; thick copper plates were cut to fit them, and both were well amalgamated. By means of this cup arrangement the three B.A. units (H, G, and flat) were connected up in multiple arc, and by means of stout copper rods the multiple arc arrangement was connected with the mercury cups with the Fleming's bridge, and so compared with the ⅓ B.A. unit, the temperature of the ⅓ being given. The following observations were taken:—

July 12th, 1889:—1/3, (18.4°) + 986.6 (b.w.d.) = M.A. + 24.6 (b.w.d.)

July 22nd, 1889:—1/3, (17.4°) + 986 (b.w.d.) = B.A. + 24.1 (b.w.d.)

Aug. 26th, 1890:—1/3, (16.8°) + 986.1 (b.w.d.) = M.A. + 23.9 (b.w.d.)

The value of a bridge wire division (b.w.d.) is .0000498 B.A. units at 15°, and the wire has a temperature coefficient of .00143. It is evident from these series of values that the ⅓ has not changed in resistance during the period of the experiments.

This comparison, however, introduced a possible error as the temperature of the bridge wire at the time of experiment was not accurately known, and this is important when nearly the whole of the bridge wire is employed. To eliminate this possible error the ⅓ was compared with four B.A. units in multiple arc. In this

case a large number of bridge wire divisions had to be subtracted from the value of the 1/3, and the whole number of bridge wire divisions entering into the calculation for the values of the 1/3 was largely reduced. The four coils in multiple arc were (F, G, H, and flat) :—

Aug. 25th, 1890 :—1/3, 16·8° + 157 (b.w.d.) = M.A. + 852·05 (b.w.d.)  
Aug. 26th, 1890 :—1/3, 16·8° + 157·5 (b.w.d.) = B.A. + 851·9 (b.w.d.)

All the four coils were at the same temperature (16·8). These values are taken from the B.A. Report, 1888.

Flat	...	...	...	1·000448
F.	...	...	...	1·000028
G.	...	...	...	·99955
H.	...	...	...	·99969

These give for the two multiple arc arrangements the values ·33330 and ·24998. The connecting rods had a resistance of ·00042, and these gave for the value of the 1/3 at 16·8° ·28537. The temperature coefficient for the coil is ·0001 per 1° C.

To measure the lengths of the wires two microscopes with scales and verniers reading to ·1 of a millimetre were set up and firmly clamped in position; the distance between them was determined by means of the beam compass and the aid of a third microscope; the distance between this and the other two being directly read off on the beam compass for set positions of the verniers. The wires were cut with a fine fret saw at the points corresponding to the position of the riders in the resistance measurements. Before weighing the wires were carefully cleaned with methylated spirits, the balance employed was the one used by Mr. Glazebrook for our determination of the specific resistance of mercury, the weights were balanced against one another, and in all cases double weighings were taken.

The specific gravity of most of the wires was measured, for this purpose distilled water was boiled and cooled rapidly, the coil of wire immersed and the beaker and its contents placed under the receiver of an air pump, which was connected up with a water pump, this was left running for two or three hours till all air bubbles had disappeared, the weight of the wire in water was determined, and a second reading taken some hours later; as the weight of wire used was from 16 to 20 grammes, fairly accurate values for the specific gravity of the several wires ought to have been obtained, and thus the value for each wire in terms of the B.A. unit for the resistance to conduction between the opposite faces of a cube of the material was found.

Resistance of Various Specimens of Wire.

Matthiessen's value reduced to 18°, using his own coefficient	Aug. 27, '90	1569	...	8·93	1750	...
		1571	...	not given	1766·6	As calculated by Fleming, Jenkin & Fitzpatrick

The first object of these experiments was to test directly in comparison with the B.A. standards samples of copper wire of high conductivities, with the view of comparing them with Matthiessen's standard. Application was therefore made to several firms for high conductivity copper wires, for which my thanks are due to those who sent samples.

A table of results is subjoined, the results for all the specimens tested are given, and they show the variation in resistance of high conductivity wires.

IV. and IV<sup>1</sup>. are the same copper, but IV. is hard drawn, IV<sup>1</sup>. is annealed; they were measured just as they were sent from the manufacturers; the same is true of V. and V<sup>1</sup>, VI. and VI<sup>1</sup>.

It will be noticed that VI. and VI<sup>1</sup>, which are of considerably less resistance than the other wires, are of higher specific gravity; the firm that sent them thus wrote of them, "it is only occasionally we come across copper as high as this or high enough to be called the highest (in conductivity) we can produce. This copper has been produced electrolytically by our ordinary process." How this copper was treated after electro-deposition I do not know, I am inclined to think from my own experience that this difference in density is due rather to the condition of the copper, than to its relative purity. Matthiessen found that very small quantities of impurities reduced the conductivity 20 or 30 per cent. and a sufficient amount of impurities to cause this decrease in density from 8·94 to 8·90, must make a larger increase in the resistance of the copper.

The temperature coefficient is stated to be different for various specimens of metal, according to their purity; Matthiessen himself seems to have been of this opinion, but the mere difference in density of the metal might be expected to effect the alteration of conductivity with the same change in temperature.

I have not been able to find any experiments bearing on this question. It is quite easy to obtain samples of wire of different density by varying the process of drawing, and the temperature coefficients of such wires might be found to be different.

Comparing V. and V<sup>1</sup> with VI. and VI<sup>1</sup>. it is seen that with this increase of density there is a distinct diminution in the effect of annealing.

$$\begin{aligned} \text{IV.} - \text{IV}^1 &= \cdot00677 \\ \text{V.} - \text{V}^1 &= \cdot00577 \\ \text{VI.} - \text{VI}^1 &= \cdot004 \end{aligned}$$

I thought it might be possible that VI<sup>1</sup> was not completely annealed, so, for a direct comparison, two specimens of VI<sup>1</sup>, which had been measured hard drawn on July 10th and 14th, 1890, were annealed; for this purpose a flat copper vessel was made of about 2 cm. height and 18 in diameter, with a closely fitting lid; the wire was packed in this between sheet asbestos, which had been previously heated up; the vessel was filled up with lampblack, the vessel was heated over a big bunsen burner and gradually cooled, the process generally took about 24 hours, the wire was found not to be oxidised at all after the process was over.

Wire.	Hard-drawn	Annealed.	Difference.
I.	1549	1510	·0039
II.	1548	1509	·0039

The difference Matthiessen obtained was ·0038.

The above method of annealing was found very effective. Silver wires, which on annealing decrease 10 per cent. in resistance, gave the same value in a second annealing as they did on the first occasion.

Wire VII. was a wire sent me by Mr. H. A. Taylor, and had to be drawn down before it could be measured; another piece of the same wire drawn down on a different occasion, gave the same value; this wire has the lowest resistance of any I have obtained; it has, too, the highest specific gravity; Mr. Taylor says of it, "That it has a higher temperature coefficient than that given by Matthiessen."

VIII. was a sample of wire obtained from Germany, and said to be electrolytically prepared; its high resistance is, I think, due to the presence of oxide, and I fused some of it up in hydrogen, and when measured partially annealed it gave the value ·1566 at 18° for the wire 1 metre weighing one gramme.

IX., X. and XI. are wires of my own preparation. Pure copper was prepared electrolytically by Messrs. Sutton, of Norwich, and supplied me in thin sheet, and this was fused down in porcelain tubes of 18 centimetres in length and 1 centimetre in diameter; the tube was fitted up in a small furnace made of sheet iron and lined with ganister; this was heated readily by a blast flame led in at the bottom; some difficulty was experienced in obtaining the copper in a solid cylinder; in the early experiments hydrogen was passed into the tube whilst the copper was being fused and was made to bubble through the molten copper; on breaking the tube, the copper was found to be full of small holes; the copper had absorbed the hydrogen at the high temperature and given it off again on cooling; on another occasion the copper was fused down in hydrogen and the tube was connected with a water pump and exhausted, and the copper allowed to cool in a vacuum; this gave a more continuous cylinder. It was found best to fuse the copper under borax, it having been previously reduced; a good cylinder of the metal was thus obtained.

I was unfortunately not able to draw down the copper for myself; this was very kindly done for me by Messrs. Smith, of Halifax, and Messrs. Johnson and Matthey. The porcelain tubes had been prepared of such a size that the cylinder of copper could be drawn without further heating; the copper, therefore, was not fused after it left my hands.

Two sheets of the electrolytically prepared copper were used

down on different days, and one was sent to Messrs. Smith to be drawn, and the other to Messrs. Johnson and Matthéy.

Wires IX. were drawn by Messrs. Smith, wires X. by Messrs. Johnson and Matthéy.

Wire XI. was drawn by Messrs. Johnson and Matthéy from a sample of copper which I prepared by electrolysis, from a pure solution of copper sulphate; the copper was deposited on a plate of copper, which had had its surface rubbed over with graphite; by this means the deposited copper was easily stripped off the plate, the other plate was of platinum, after a time the solution was changed; the deposition was very slow, as it was thought that there would be less likelihood of copper sulphate getting in between the layers of copper.

The deposit was boiled with dilute sulphuric acid and then in water, and was afterwards fused down as above described.

Wires IX. were measured as received, this accounts for the close agreement between the two determinations. Wires X. and XI. I had to draw down further to measure them on my bridge.

Wires X. (2.) and XI. were drawn down with great care and not so much as X. (1.)

Below is a table of the measurements made for the determination of their specific resistances.

Wire.	Value of $\frac{1}{s}$ .	Temp	Weight of wire.	Length of wire for determination of resistance.	Length cut and weighed.	Resistance of gramme per metre.	
IX. (1.)	·28547	17·9°	20·388	192·1	192·5	1574	18·3°
„ (2.)	·28541	17·4°	20·153	192·4	190·45	1569	17·5°
X. (1.)	·28550	18·2°	19·708	189·3	188·8	1577	18·6°
„ (2.)	·28536	16·8°	20·252	192·39	192·34	1561	17·1°
XI.	·28535	16·7°	20·262	192·11	192·51	1563	17·2°

These values reduced to a common temperature of 18° are:—

IX. (1)	...	·1572	
IX. (2)	...	·1572	Mean value
X. (1)	...	·1573	·1571
X. (2)	...	·1569	B.A. units.
XI.	....	·1569	

Thus ·1571 B.A. units is the resistance of a metre of hard-drawn copper wire at 18° weighing 1 gramme.

Matthiessen in the B.A. Report\* gives as the resistance of a gramme metre at 0° ·1469 B.A. units.

I have calculated from this the value at 18°, using the temperature coefficient that he gives in his paper on the influence of temperature on the conducting power of metals. I have taken no account of the terms in  $t^2$  as they practically cancel one another.

$$R. \text{ (at } 18^\circ) = R_0. (1 + \cdot0038701 t)$$

$$R. 18^\circ = \cdot1571.$$

This is the same value that I have obtained as the mean of my own observations.

All my observations were taken at the temperature of the room, and in the table above, the values for the different wires are given at the observed temperature, and then all reduced to a common temperature of 18° C. Most observations of this character are taken at the temperature of 0° C., but on the whole it seemed more satisfactory to work at the temperature of the room. In the comparison of the B.A. units I have found that with a difference of temperature between coils which are connected by thick pieces of copper there is always conduction of heat, and it is impossible to tell accurately what is the real temperature of the coils.

My observations were made in the B.A. room at the Cavendish Laboratory, which has a north aspect, and often the temperature does not alter more than a few tenths of a degree, whilst the temperature of the coil baths often remains perfectly steady for several consecutive days. I cannot find any observations of Matthiessen's at 0° C; certainly his observations on copper were made at 18°, and, consequently, if the value given by him at 0° C. has been obtained by the use of a temperature coefficient, my value might be expected to agree with his at 18°, the temperature of his observation, supposing the samples of copper of the same character.

Matthiessen's results are given in terms of a gramme per metre, also for wires of metre length and 1 mm. in diameter.

In a paper in the *Philosophical Magazine*, Matthiessen gives us the value for hard-drawn copper in these terms as,

$$\cdot02104 \text{ B.A.}$$

From his value for the Gramme metre, using the sp. gravity 8·95 given by tables, the same quantity was calculated but gave the result ·0209; in a note added, he states that had he used the sp. gravity 8·91, his results would have been more nearly alike; but a sp. gravity 8·90, I find, would give an almost identical value.

This would show then that Matthiessen's own table calculated for values obtained by comparison with hard-drawn silver is accurate; I have tested silver wires, but have not had time to

draw up the results in tabular form; and I obtained an almost identical value for hard-drawn silver wire, as supplied me from Messrs. Johnson and Matthéy, as is given by Matthiessen for the resistance of a gramme per metre.

It will be observed that wires IX. have the specific gravity 8·90, and give a value in terms of B.A. units for a cubic centimetre of the material identical with Matthiessen's value; this value is not given directly by Matthiessen, but is calculated from his results by Fleming Jenkin and given in his table in his book "Electricity and Magnetism," it is 1,652. I have calculated it from Matthiessen's value given in the *Philosophical Magazine*, and get the number 1,653. Using the same temperature coefficient as before, the resistance of a cubic centimetre of hard-drawn copper is 1766·6.

On comparing the values for wires IX., X. and XI. in these terms, the results do not agree so well together as when expressed in terms of the gramme metre; there is a corresponding difference in the values of the specific gravities, these latter have been very carefully determined, repeated with the results given.

Wires, therefore, of the same resistance expressed for grammes per metre may give a very different result, when expressed as per cubic centimetre; attention has been drawn to this fact in the discussion on the Elmore copper in the *Electrician*\*. M. Roux, of Paris, in a letter gives the following table for high conductivity wire, from a paper of M. Hospitalier in *L'Electricien*, 1887; this paper I have, unfortunately, not been able to see.

Density ... ..	8·897	9·32	9·6
Conductivity equal volume	102·4	106·7	110·8
Conductivity equal weight	101·7	101·2	101·6

What is 100 in the conductivity units is not expressed. M. Roux thinks that the former is the more rational method of expressing the result, i.e., for one of equal volume.

Matthiessen expressed all his results in terms of equal weight, justifying it by the greater accuracy obtainable when working with small weights of wires. Small errors in the value of the specific gravity are easily made, and cause a similar error in the result for equal volumes of different wires; unless working with long lengths of thick wire the weight of the wire is small, and the weight of the water displaced cannot be determined within ·5 to 1 milligramme, and that only with care: this error in ·5 of a gramme means only an accuracy of 1 in 500. The values given in my table are probably correct to 1 in 1,500 or 1 in 2,000, as the weight of water displaced was in all cases over 2 grammes. Results, therefore, for resistances of wires of equal weight are the most trustworthy and, I think, also the most satisfactory if used to express the resistance of a material and not of any given wire.

Wires X. (1) and X. (2) are of the same copper, but drawn down separately X. (1) was beginning to fray, and another specimen of the same copper drawn down still further had on this account to be rejected; this has affected the resistance value expressed in both ways. Thus

X. (1)	...	·1573	...	1767
X. (2)	...	1569	...	1751

but much more so when expressed for equal volumes. In both the copper is of the same quality.

It will be noticed that with increase of specific gravity there is a decrease of resistance, even when the results are expressed for wires of equal weight; the resistance diminishes, therefore, more rapidly than the density increases. Wires, therefore, of the same quality may, in consequence of a difference in drawing, have a different density, and so the results expressed in terms of equal volume will differ considerably; while those for equal weight are the same, or approximately so.

The values obtained for IX., X. and XI. are so nearly identical, that it is not unfair to conclude that they are samples of pure copper; their value is identical with that obtained by Matthiessen at, I believe, the same temperature. The greater difference obtained at 0° C. between Matthiessen's value and samples of copper tested now at that temperature, is probably due to the fact that Matthiessen's value was not determined at 0°, but reduced in value for that temperature from observations, as stated above, at about 20° C.

The higher conductivity or less resistance for the two samples given in the table is due not to increased purity in the preparation of the copper, but in the difference in the process of preparation, whereby a sample of greater density is obtained than results from the working up of small quantities of copper in the laboratory.

A sample of copper has been prepared by chemical means with the help of my friend, Mr. Skinner, but has not yet been measured.

The discussion on this paper and others will be given in a later issue.

## NOTES ON THE VULCANISATION AND DECAY OF INDIA-RUBBER.

By WILLIAM THOMSON, F.R.S.Ed., F.C.S.

(Read before Section B., September 10th, 1890.)

UNDER ordinary conditions India-rubber for vulcanising is usually mixed with sulphur and heated to a high temperature, when chemical combination takes place between the sulphur and the

\* B.A. Report, 1864, or *Phil. Mag.*

\* *Electrician*, December 7th, 1888.

rubber, producing a much more valuable compound for ordinary purposes than unvulcanised rubber, the former remaining plastic at very low temperatures and firm at high temperatures, whilst the latter becomes hard and quite soft respectively at those temperatures.

In making cloth for waterproof garments another method is employed for vulcanising the rubber, viz., by wetting its surface with a mixture of somewhere about 5 to 10 parts of chloride of sulphur dissolved in 100 parts of bi-sulphide of carbon and then heating the fabric gently to evaporate away the excess of these substances: the rubber-covered cloth cannot be heated to a high temperature like the rubber alone, because the heat would be liable to injure the cotton, silk or wool of the fabric, or destroy or injure the colours.

The bi-sulphide of carbon softens and penetrates the fine layer of rubber, carrying with it the chloride of sulphur dissolved in it, and it is generally supposed that the chloride of sulphur breaks up, the sulphur combining with the rubber, producing vulcanisation, and the chlorine combining with the hydrogen producing hydrochloric acid, which is liberated. This reaction is clearly not the correct one, and it is probable that the reverse is more in accordance with the facts, viz., that the chlorine of the sulphur chloride combines with the rubber, producing vulcanisation, leaving the sulphur in the free state, or only partially in combination with the rubber, because in rubber vulcanised by the cold process I have found free sulphur to be present.

From a piece of rubber-covered cloth I separated the rubber and submitted it to analysis by mixing it thoroughly in small pieces with pure sodium carbonate and igniting, then dissolving the whole in water and adding to it peroxide of hydrogen previously treated with excess of barium-chloride (to separate sulphuric acid or sulphates). The peroxide ensures the conversion of the lower oxides of sulphur into sulphuric acid, whilst the excess of barium chlorides precipitates the sulphuric acid in the solution which is then weighed as barium sulphate.

Another portion of the made up solution was neutralised and the chlorine present titrated. The rubber, previous to ignition as above described, had been well boiled in water and dried to separate any hydrochloric acid which might be present, but only a faint trace of chlorine compound could be thus separated from the rubber.

The total sulphur present in the rubber amounted to 2.60, and the total chlorine to 6.31 per cent.

The yellow-coloured sulphur proto-chloride is best adapted for vulcanising, because it does not act too strongly upon the rubber, whilst the dark coloured chloride of sulphur containing, as it does, a large quantity of the higher chlorides of sulphur, is liable to render the rubber quite hard by vulcanising it too much. The theory generally adopted to explain this is, that these higher chlorides break up easily, liberating their sulphur which thus combines in greater quantity with the rubber, but my experiments and analyses prove that it is chiefly the chlorine and not the sulphur of the chloride of sulphur which produces the vulcanisation.

A rubber substitute, much used at present, is produced by acting on vegetable oils such as rape, linseed, &c., with a mixture of chloride of sulphur and bisulphide of carbon; the oil becomes converted into a solid substance resembling India-rubber to some extent, but being much more brittle. This body is now used in large quantity for mixing with India-rubber for the purpose of cheapening its production. On analyses of some samples of this material I have invariably found that it contained a much greater proportion of chlorine than of sulphur, and this process, therefore, is a vulcanisation by chlorine rather than by sulphur.

Recently I analysed three samples of rubber substitute, the one termed "special," another "spongy" India-rubber substitute, the third being similar to the first in appearance. The first contained of sulphur 3.4 and of chlorine 7.6 per cent.; the second contained of sulphur 4.56 and of chlorine 8.22, and the third 2.67 of sulphur and 7.90 of chlorine per cent.

These rubber substitutes contain considerable quantities of oily matters soluble in ether which I have also found to be chlorine and sulphur compounds of the oils. The first yielded 20.0 per cent., the second 14.3, and the third 11.5 per cent. of these thick oily matters soluble in ether. This oily substance from the first sample contained 2.6 per cent. of sulphur and 6.1 per cent. of chlorine, whilst that from the second contained 2.97 and 6.87 per cent. of sulphur and chlorine respectively.

Some rubber manufacturers regard this oily matter as injurious to the rubber, and reject any substitute which contains any considerable proportion of it. I have found, however, by experiment, that this oily compound, instead of acting injuriously on India-rubber, actually acts as a preservative of it. Some rubber threads were smeared with this oily extract, some with ordinary (unvulcanised) rape oil, and some left untreated; these were put into an incubator at 150° Fahrenheit for a few days, when it was found that the oil-treated rubber was quite soft and rotten, whilst the other two had remained sound. After a few days, more the original rubber thread had become quite rotten, whilst the threads smeared with the oily part of the vulcanised oil remained quite sound.

The first and second samples of rubber substituted were examined for soluble chlorides or hydrochloric acid, by boiling in water, the first gave 0.18 per cent of chlorine soluble in water, and the second 0.05 per cent.

It has been known for some time that copper salts exert a most injurious influence on India-rubber; copper salts are sometimes used in dyeing cloth which are afterwards employed for waterproofing with India-rubber, and it seems quite astonishing what a

small quantity of copper is required to harden and destroy the rubber; and the destructive effect of copper is further enhanced if the cloth contains oily matters in which the copper can dissolve. As an example, here is a piece of cloth alleged to have damaged the thin coating of India-rubber on it. I found it to contain copper, and with a view of demonstrating this point I took one piece in its original condition; to the end of this I pasted a similar piece of the cloth from which the oily and greasy matters had been removed by ether, and to the end of this, again, I pasted another piece of the same cloth from which I had removed both oily and greasy matters and copper; these three pieces joined into one were then coated in the usual way with India-rubber, and then hung in an incubator at 150° Fahr.; in the course of a few days the rubber on the original cloth had become soft, and it then hardened and became rotten and useless; the second piece from which the greasy matters had been removed then became quite hard and rotten, whilst the part from which both greasy matters and copper had been removed has remained in a perfectly elastic and good condition.

Prof. Dewar observed, accidentally, that metallic copper when heated to the temperature of boiling water in contact with the rubber, exerted a destructive effect upon it. With a view of finding whether this was due to the copper *per se*, or to its power of conducting heat more rapidly to the rubber, I laid a sheet of rubber on a plate of glass and on it placed four clean discs, one of copper, one of platinum, one of zinc, and one of silver; after a few days in an incubator at 150° F., the rubber under the copper had become quite hard, that under the platinum had become slightly affected and hardened at different parts, whilst the rubber under the silver and under the zinc were quite sound and elastic. This would infer that the pure metallic copper had exerted a great oxidising effect on the rubber, the platinum had exerted a slight effect, whilst the zinc and silver respectively had had no injurious influence on it. A still more curious result was this, that the rubber thus hardened by the copper contained no appreciable trace of copper, the copper therefore presumably sets up the oxidising action in the rubber without itself permeating it. I have pleasure in acknowledging the assistance rendered to me in these experiments by my assistant, Mr. Frederick Lewis.

#### A NEW DIRECT READING PHOTOMETER MEASURING FROM UNITY TO INFINITY.

By FREDERICK H. VARLEY, M.I.E.E., F.R.A.S.

(Read before Section A, September 10th, 1890.)

The object I had in view in designing this apparatus was to meet a want that has been felt by electrical engineers and others interested in the measurement of light, namely, a convenient form of apparatus as handy to manage as the usual set of measuring instruments which are provided, so as to take its position along with the voltmeter, the ammeter and the wattmeter.

Incandescent lamps are now made of such generally uniform construction that if we can, with facility, measure the light produced, we can readily deduce, for all practical purposes, the amount of current delivered, and thereby determine the general efficient working of the installation. Or, conversely, if we know the current in watts passing through a glow lamp, we can determine the suitability of the filament for the purpose required, provided we can readily obtain photometric measurements. The conditions imposed are, that the instrument should be portable, have a range from one candle-power to that of the electric arc, that the light to be measured, and that of the standard, should be exactly at the same distance from the screen.

This instrument consists of two discs, each pierced by two semi-ring-shaped windows or apertures. These openings extend to the half circle (180°); both are of the same width, 1 inch broad. The openings in the two discs are placed in reverse positions to one another, so that if one half-ring is opened to its full extent (180°), the other half-ring is entirely closed; or, if the discs are shifted to an intermediate position, both apertures will be opened to an equal extent—namely, 90°.

If, in this position, the discs are rotated, it is obvious that an equal amount of light can pass through both rings, but if the light to be measured is as 1 to 17 C.P., then the angular length of the two apertures must bear a proportionate ratio in order that the two shadows shall be of equal density; and accordingly, one aperture will be open to the extent of 10° for the brighter light, whilst that of the standard light is opened 170°. Instead of dividing the circle into the conventional 360°, I divide the half circle into 2,000 parts, this giving a range from 1 to 1,999, or 2,000 in round numbers. By still farther shifting the discs, this aperture may be entirely closed and read up to infinity. The divisions of the half circle are numbered from left to right and right to left, showing at once the fraction values of the angular extent of the opening or arc, and thereby giving the values of the light.

In order to make the discs turn one upon the other, I have devised a modification of the Fergusson paradox; that is to say, the discs are carried by independent shafts, one of which is hollow to allow the central axis to turn within it; at the end farthest from the discs a cog wheel is fixed to each axis. By means of a sliding link the two wheels can be brought into gear with the axis also provided with cog wheels, each being the same diameter, but one is cut with 100 teeth, whilst the other has 99 teeth. Thus, upon rotating the discs, each revolution of the gearing wheels advances the discs, and so changes the proportion of the openings,

one decreasing whilst the other increases, and *vice versa*; this we can do until the two shadows are of equal density, or approximately so, when the final adjustment can be given by hand. Behind the windows two hollow cones are placed which have their axes directed to a point common to both, but at some distance in front of the discs where the two shadows fall upon the screen. A second or back screen is then placed at the mouth of these cones, over which it fits, and effectively cuts off one light from the other, so that on one side is, say, the electric light, and on the other the standard candle. The light from both passes through axes of their respective cones, and through the discs, and on to the screen upon which the shadow image is cast.

This apparatus, in its present form, has only just been received from Mr. Lege, who has constructed it for us, and Mr. Friese Greene and myself are arranging a series of experiments which, we hope, will prove useful in photography.

In the course of the discussion, Sir WILLIAM THOMSON stated that it was a question whether integration by sensibility is the same as if continuous light be employed. There is a general idea that they are the same, but the point had not been, so far as he knew, absolutely settled. He had compared sunlight with the light of a candle by means of a pinhole one millimeter in diameter at a distance of a few yards from the paper screen, whilst the candle was at a distance of a few inches; he employed the shadow method. He considered the piece of apparatus exhibited by Mr. Varley to be well devised, and hoped that at the next meeting of the association he would be able to give his results by both methods.

Prof. J. D. EVERETT said that in colour experiments it is assumed that the penumbra method, such as just presented, holds true, because of the consistency of the results.

Prof. G. F. FITZGERALD remarked that it has been calculated that if the energy of all the solar radiations falling upon the earth could be conserved and utilised, each square metre of the earth's surface would afford sustenance to ten individuals, so that—as someone, not an Irishman, had expressed it—"there would be so many people that there would not be room for anyone."

Dr. OLIVER LODGE stated that experiments had been made in Germany showing that a curious physiological effect of flickering light under certain conditions was the production of colour, and that the colour disappeared when the motion was increased.

Mr. FREDERICK VARLEY, in reply to the speakers, said that he was glad to hear from Sir William Thomson the results of his experiments in comparing the light of the sun with a standard candle, and thanked him for the suggestions and encouraging opinions he had expressed. He would point out that the great object he had in view in constructing this apparatus was to obtain a portable and readily worked instrument which could be set up in any room or laboratory. The working of the Bunsen photometer required a room more than a 100 feet long in order to measure a 10,000 candle-power arc light. After speaking of Prof. Ayrton's photometer, he pointed out that by means of the new apparatus, measurements of the electric arc light could be obtained in the space occupied by an ordinary table.

The following is an illustrated description (for which we are indebted to the *Photographic News*) of the apparatus referred to in the foregoing paper:—

Two discs, perforated by semi-ring-shaped openings, the breadth of which are equal, as shown in fig. 5, are mounted on an axis with

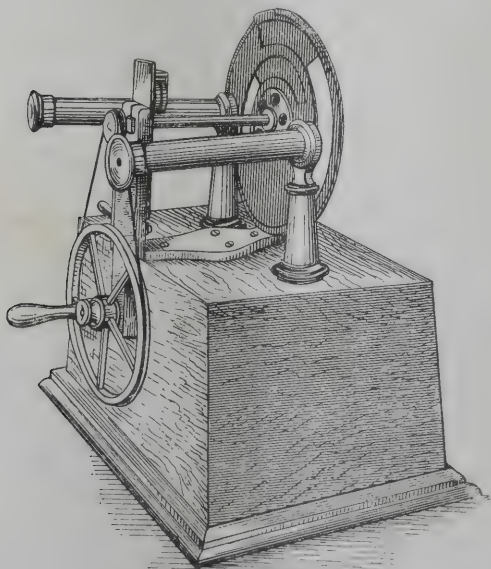

FIG. 4.

their openings reversed, so that when the outer half-ring is fully open (extending to 180°) the inner ring is entirely closed; or if the outer half-ring is open to 90°, then the inner ring will be opened to the same extent, as shown in fig. 6. In that case, when the discs are rotated, two complete circles are formed, through

which an equal amount of light will pass. Again, as in fig. 7, the outer ring is nearly open, and the inner one only partially so. As before, two rings are formed upon rotation, but the amount of light which passes through will be unequal, being, in fact, directly proportionate as the extent of the degrees of arc of the openings are to one another. If, say, the outer ring is opened 160°, and the

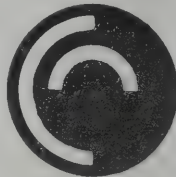

FIG. 5.

FIG. 6.

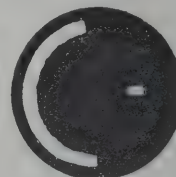

FIG. 7.

inner 20°, in order that the more intense light passing through the inner circle shall balance the standard light passing through the outer, all that has to be done is to read off the respective degrees and write them down in the form of fractions—that is,  $\frac{20}{160} = \frac{1}{8}$  from this we ascertain that the light is eight times more intense than the standard. Instead of the conventional division of the circle, we divide the half-circle into 2,000 parts, for the purpose of obtaining a finer or more extended range of reading up to 1,999 times; these divisions, by means of a vernier, can be further subdivided ten times, and read up to 20,000 candles in round numbers.

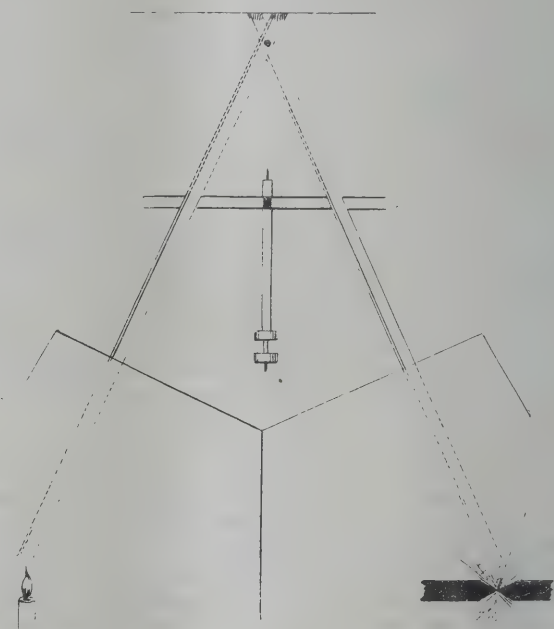

FIG. 8.

The breadth of the semi-ring-shaped windows in this instrument is one inch, and in front of the discs are two equal collimators, one of which projects a disc with a black centre, and the other a corresponding luminous spot. They are regulated so that when the light falling upon the screen from both sources is equal, a uniform disc is obtained; but if one or the other preponderates, a disc with a grey spot, or a grey marginal ring with a bright spot, indicates which of the two sources of light reaching the screen predominates.

In order to regulate this, it is necessary to open one of the windows and close the other until a balance is obtained. This is effected by bringing into play a modification of the well-known Fergusson paradox: the rear disc is carried by the central axis, and the front disc by a long sleeve fitting over it; both the central axis and the sleeve are provided with tooth wheels. Above these is an axis which carries two wheels, one with a hundred teeth, and the other with ninety-nine teeth, which are readily placed in or out of gear by a jointed lever; when in gear they cause the two discs to shift or turn upon each other, and so open or close the windows. It is convenient in some cases to dispense with the collimators, and determine the values of the light by comparison shadows, in which case a T-shaped screen is employed pierced with two holes each a circular inch in diameter, the centres of which are of a distance apart which corresponds with the mean diameter of the circular windows through which the light passes on to the screen. The middle partition forming the T prevents one light from interfering with the other. The apparatus is set in rotation by turning a band wheel, and the windows adjusted until the two shadows balance. The values are read off from the divided scale of 2,000 parts, which is numbered from left to right, and right to left, giving at once the fraction values of the ratios of one aperture to the other.

A COMPARISON OF A PLATINUM THERMOMETER  
WITH SOME MERCURY THERMOMETERS AT LOW  
TEMPERATURES.

By E. H. GRIFFITHS, M.A., Sidney College, Cambridge.

(Read in Section A, September 9th, 1890).

THE paper describes the mode of constructing an air-tight platinum thermometer for use at low temperatures. The thermometer was graduated by means of the freezing and boiling points of water, and as regards intermediate points Regnault's determinations of the temperature and pressure of aqueous vapour were adopted. The precautions observed in the construction of the apparatus, and in the method of observation, are described. The thermometer was tested by comparison with a number of thermometers standardised at Kew. The curves, showing the result of these determinations, are in remarkably close agreement, and when the observations were sufficiently numerous it appeared possible to calibrate the bore as accurately as by the usual more laborious process. The further advantage of this method is that thermometers can be compared under the conditions in which they are to be used.

In a communication to the Royal Society read on June 19th, 1890, I described a method of constructing and graduating platinum thermometers and gave a table of boiling and freezing points for various substances lying between 100° and 500°, determined by means of these instruments.

Subsequent observations indicate that a slight change appears to be taking place in the readings of these thermometers, I attribute this (1) to alterations in the glass, (2) to presence of moisture in the tube—the asbestos roll on which the spiral was wound being highly hygroscopic. I therefore decided to construct a thermometer in which there should be no contact between the glass and the platinum, and which should be thoroughly dry and hermetically sealed.

I was unable to discover any suitable non-conductor capable of resisting high temperatures; but in Anthracene (melting point 213°) I found a substance suitable in every respect for use at low temperatures. I subjected a sample to severe tests and, up to a temperature of about 130°, found it to be a better insulator than paraffin.

The leads to the coil were constructed of silver, the inner one a rod and the outer a tube. The resistance of these leads was about .001 ohm and, therefore, any change in the external resistance, caused by change of temperature, might be disregarded. The silver leads approached to within about one inch of the spiral and were connected to it by moderately thick platinum wires; thus a flow of heat from the spiral to the silver was diminished. The wire forming the coil was about fifty-six inches in length and had a diameter of .005 inch. The spiral was about 2 inches long having a resistance of about 13.5 ohms at 0° C., and the external diameter of the covering tube was about .3 inch. The ends of the Asbestos roll were made of greater diameter than the portion on which the spiral was wound, and thus there was no glass contact. The tube and contents were heated up to a temperature of several hundred degrees and dried air passed through it for some hours. It was then exhausted and the open end placed under the surface of melted Anthracene, which was allowed to rise until nearly in contact with the coil. When cool, the whole of the thermometer, from the spiral to the upper end (about thirteen inches) was a solid mass, while the spiral and asbestos roll were perfectly dry and in an almost vacuous space. I have taken nearly six hundred observations with this thermometer and cannot detect any signs of change. When the lower part was undergoing rapid changes in temperature, thermo-electric effects showed themselves, but by reversing the battery and galvanometer connections during each reading these effects were eliminated. A low resistance galvanometer was used, and the current, which passed through the thermometer when determining its resistance, did not exceed one hundredth ampere. To illustrate the closeness of the agreement in the results obtained at different times I give the following determinations of the resistance at 100° taken in the usual manner by means of a hypsometer with manometer attached. Full corrections were made in the barometric reading, and the results reduced to lat. 45°.

Date.	Temperature.	Resistance (after corr. for temp. of coils).
July 26 ...	100°C.	18.2029
" 27 ..	100°C	18.2034
August 12 ...	100°C.	18.2025
" 13 ...	100°C.	18.2031
mean		18.2030

The expression for the platinum temperature by this thermometer

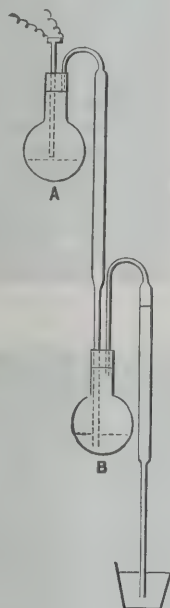

$$\text{was } \frac{(R - 13.5219)}{4.6811} \times 100, \text{ again } \frac{R_{100}}{R_0} = 1.3462,$$

almost exactly agreeing with the coefficient of the wire in Mr. Callendar's air thermometer (Phil. Trans. A 1887).

Mr. G. M. Clark, B.A. (Sidney Coll. Cambridge), now joined me in the investigation, and as we proposed to use this thermometer for the calibration and graduation of mercury thermometers between

0° and 100°, we decided to obtain intermediate temperatures by means of Regnault's numbers connecting the temperature and pressure of aqueous vapour. For this purpose we constructed a large iron tank with two plate glass sides, holding about 16 gallons of water, and through two holes bored in the bottom, inserted two barometer tubes, the upper 16 inches of each being within the tank. One of these was used as a standard barometer, and was prepared with great care, the distilled mercury, with which it was filled, having been boiled in the tube for more than 6 hours. The internal diameter of the tube was 14 m.m., and the absence of any meniscus was very marked. If the level of the surface of the water in the tank was below the top of the barometer, and the water warmed, the sublimation of mercury in the vacuous space was observable. The second barometer was made from the same length of tubing as the first, and communicated at its upper extremity with a small flask (A), in which was placed the platinum thermometer.

Distilled water was boiled in vacuo for some hours, to expel all traces of air. The flask and barometer tube were then exhausted by means of an air pump, and the lower end of the tube placed in a flask (B) containing the previously boiled water, which rushed up, filling the tube and flask (A).

The water remaining in (B) was then boiled until this flask and a bent tube passing from it into a basin of mercury, 30 inches beneath, were completely filled with steam, and, on cooling, the height of mercury in the tube enabled us to determine that the pressure on its surface was that of aqueous vapour only. The water in the upper flask was then boiled for many hours, and only allowed to cool occasionally to permit of the water in the lower flask being boiled away. To prevent access of air, the steam was driven off through the mercury. When the water in flask (A) was reduced to about a tablespoonful, the boiling was stopped, and the level of the mercury was raised until it flowed back first into flask (B) and thence into the barometer tube, as flask (A) cooled.

The open end of the barometer tube was then sealed, the flask (B) replaced by a small cup of dry mercury, and the end of the tube opened below the surface. The water remaining on the top of the column was driven back into the flask by pouring hot water over the tube.

During our experiments, water occasionally collected on the mercury, but by means of a concave mirror it was driven back into the flask; the mirror was of course removed sometime before an observation was taken.

The tank, filled with water, was maintained at any required temperature by means of a gas regulator. The lower parts of the barometer tubes were screened by sheets of asbestos, and the two cups were connected by a small siphon. The glass sides of the tank were covered with white paper to prevent radiation, openings were left for observations, during which, the water in the tank was kept in a continual state of agitation by the oscillation of a large paddle driven by a water motor. The paddle, fixed in one corner of the lid, swept across the tank driving the water before it and lifting it at the same time. We have tried several forms of stirrers, and we believe this to be a more effective form than a screw or a plunger.

The difference in the height of the mercury in the two barometer tubes, was ascertained by the kathetometer G. 33, in the Cavendish Laboratory, and by means of it, readings could be taken to .50 m.m. Care was taken to bring both levels horizontal before each observation.

As the co-efficient of expansion of the kathetometer scale was unknown, and the temperature of the room usually about 20°C., we decided to compare it with the standard scale R, whose co-efficient of expansion and scale errors had been determined by the Standards Department of the Board of Trade.<sup>1</sup>

<sup>1</sup> Standard metre, verified June, 1882, designated R in Mr. Chaney's report.

Twenty-one comparisons were made (greatest divergence from the mean .10 m.m.) and the result was as follows:—300.35 m.m. on kathetometer scale at 20° (=300.35489 of Board of Trade Standard (S.S.) at 0°.

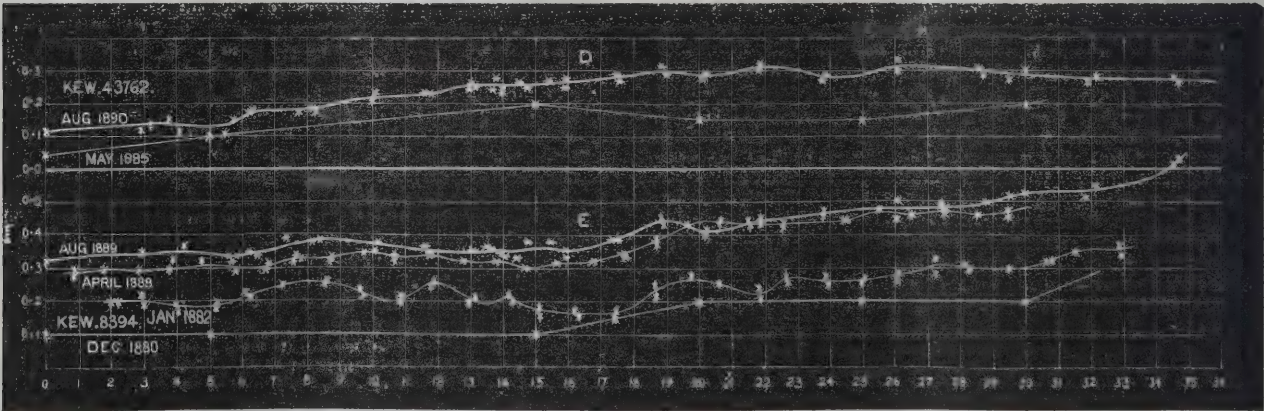

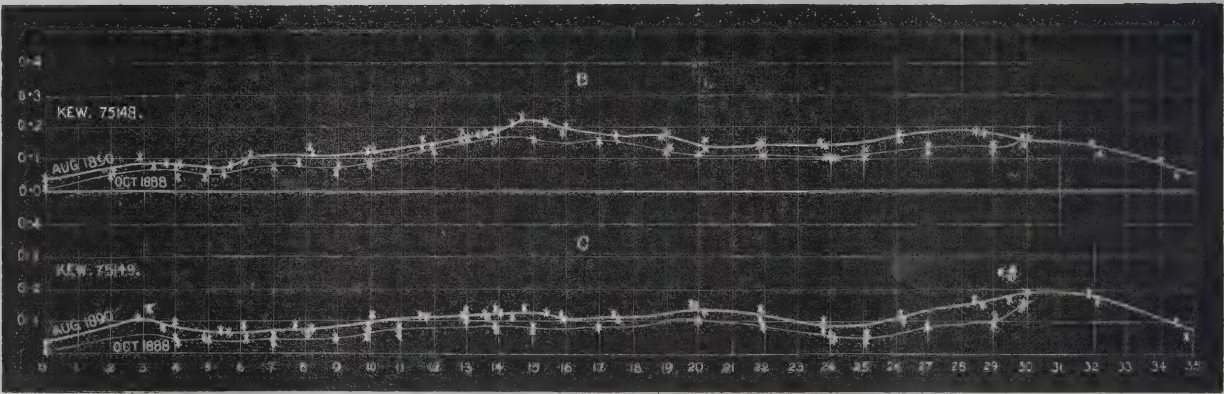

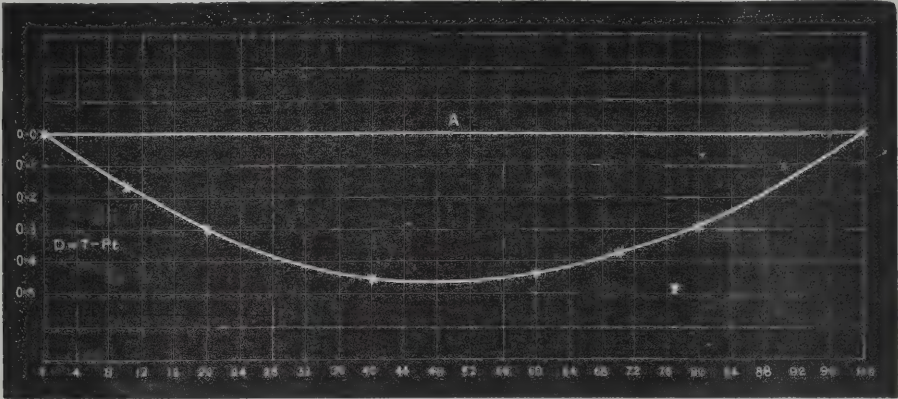

Thus no scale correction was necessary.  
The difference (D) of the mercury columns was corrected for temperature, pressure of mercury vapour and latitude and the resulting length denoted by  $D_0$ : the temperature corresponding to  $D_0$  was deduced from the very full table given in Part 3 of Carnelly's "Melting and Boiling Point Tables."

The extremities of the curve at (0° and 100°) having been determined, it was only necessary to get points between 30° and 80°.

Ninety observations were taken, and although occasional diver-

$y = .018795t - .0001991t^2 + .000,000,111.5t^3$ . the curve itself is shown in Chart A.

We proceeded to test our conclusions by comparison with thermometers standardised at Kew; for this purpose a rotating annular ring, through the centre of which the platinum thermometer passed, was inserted in the lid of the tank, in such a manner that the mercury thermometers, fixed in holes bored near its circumference, could successively be brought into the field of view of the kathetometer without any re-adjustment of the telescope; the thermometers were then read by one observer, whilst the platinum resistances were taken by the other. The freezing points were not, however, determined by this method, but by direct immersion in powdered ice, adopting the precautions recommended by Guillaume in his *Thermometrie de Précision*.

gences presented themselves, the mean path gives a curve which we believe to be within less than .02° of the true path at all points. It agrees closely with the curve obtained by Mr. Callendar from the parabola  $1.57 \left[ \left( \frac{t}{100} \right)^2 - \frac{t}{100} \right]$ , by measuring one tenth of the ordinate along the abscissa.<sup>2</sup>

meter temperatures.

The following equation, however represents its path more accurately.

<sup>2</sup> It must be remembered that Callendar's difference curve gives the connection between platinum and air-thermometer temperatures, whilst Regnault used a mercury thermometer (M.A.S. XXI.) and thus curve A gives the relation between platinum and mercury thermometer temperature.

The following curves were then drawn, which indicate the result of the comparison of our platinum thermometer with those standardised at Kew.

Curve.	Thermometer, Kew No.	Standardised.
B.	75148	October, 1888.
C.	75149	October, 1888.
D.	43762	May, 1885.
E.	8394	Dec., 1880; Jan., 1882; April, 1888.

All these thermometers were made by Hicks, the first three were kindly placed at our disposal by Mr. R. T. Glazebrook, the last is

one of those referred to by Mr. W. N. Shaw in a communication to the B.A. during the Bath Session, the successive curves of which, then exhibited by him, he has kindly allowed us to copy.

In these diagrams the abscissæ represent the temperature, in the strong curves, that obtained by us, and in the faint, that obtained by Kew; the ordinates in each case being the divergence of the actual readings from these results. Where crosses occur at almost identical temperatures they indicate observations separated by a considerable interval of time, in no case did less than 20 minutes elapse, whilst in others several days.

Three only of our observations are unrecorded on these charts, and in each case, owing to imperfect light, interruptions, &c., these experiments were regarded as doubtful before their results were deduced.

The gradual rise of the zero point is clearly indicated; apparent discrepancies are probably due to the fact that the Kew determinations are less frequent than ours, and as a consequence many of the smaller deviations have escaped notice.

The results show:—

- 1st. That thermometers whose range does not include 0° and 100° may have certain fixed points determined by this method.
- 2nd. That an actual calibration of a mercury thermometer can also be readily accomplished.
- 3rd. That the platinum thermometer, properly constructed, may serve as a standard by which to trace the changes which may take place in mercury thermometers.
- 4th. That since the readings of the platinum thermometer are independent of the extent of the stem-immersion, it can be conveniently employed for the graduation of thermometers partially immersed, as in ordinary use.

During the past few days, we have calibrated about twenty thermometers by this method, and we believe the results to be satisfactory in all cases.

### REPORT OF THE COMMITTEE ON ELECTRICAL STANDARDS.

(Read in Section A, September 9th, 1890).

#### LEGAL OHMS.

THE work of testing resistance coils has been continued at the Cavendish Laboratory. A table of value found for the coils is appended.

No. of Coil.				Resistance in Legal Ohms.	Temperature.
Nalder	...	1577	C.L.C. 189	·99981	16·9
Nalder	...	1573	C.L.C. 190	1·00089	16·9
Nalder	...	1579	C.L.C. 191	1·00041	16·9
Edison Swan	...	16	C.L.C. 192	·99846	13·9
Elliott	...	229	C.L.C. 193	1·00028	16·9
Elliott	...	230	C.L.C. 194	1·00021	16·9
Simmons	...	...	C.L.C. 195	·99992	16·8
Nalder	...	1626	C.L.C. 196	1·00045	15·3
Nalder	...	1627	C.L.C. 197	1·00056	15·3
Nalder	...	1628	C.L.C. 198	1·00058	14·8
Nalder	...	1580	C.L.C. 199	1·00072	15·3

#### B.A. UNIT.

It would be of considerable advantage in the testing if all the coils were made of a uniform size. The original Standards of the Association measure  $6\frac{3}{4}$  inches from the bottom of the case to the underside of the horizontal portion of the copper connecting rods, while the vertical portion of these rods is 8 inches in length. These dimensions should be adopted in all coils sent to be tested; if this be done the baths, &c., made to hold the standards hold the coils equally well, and the additional convenience in testing is very great.

The original Standards of the Association have again been several times compared among themselves.

The results of the comparisons appear to show that while the coils A, B, C, D, E, and Flat have remained constant relative to each other, the three platinum silver coils F, G and H have changed.

The change in F was referred to at the end of the Report in 1888, and is now very large. The coil has increased in resistance by about ·0006 B.A. units; G, on the other hand, has fallen by about ·0002 B.A. units, and H by about ·0001 unit. The evidence for these various statements is given in an appendix to the Report by the Secretary.

It is perhaps worth remark that in each case the change either took place during the time that the coil was immersed in ice or was found to have happened when the coil was next measured after its removal from the ice.

The legal ohm coils have not varied relative to Flat.

The investigations into the resistance of copper have been continued by Mr. Fitzpatrick. The Committee desire again to thank the gentlemen who have rendered him assistance in various ways.

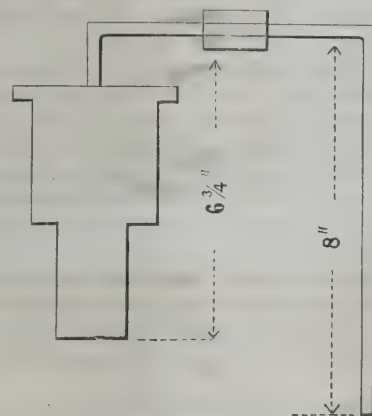

Mr. Fitzpatrick has examined various specimens of copper supplied him as wire. He has also examined copper prepared for him as pure by Messrs. Sutton, as well as some which he prepared himself electrolytically from carefully purified copper sulphate. These last two specimens lead to practically the same value as that obtained by Matthiessen for the specific resistance of copper—viz.,  $1767 \times 10^{-9}$  B.A. units at 18°, the specific gravity of these specimens is about 8·90. Two wires supplied to him have, however, a distinctly lower resistance: the value for one being  $1731 \times 10^{-9}$  and for the other  $1724 \times 10^{-9}$ ; a difference in the one case of 2 and in the

other of 2·4 %. The specific gravity of the first of these wires is 8·940 and of the other 8·946, and Mr. Fitzpatrick assigns the increased conductivity to increased density rather than to greater purity.

Matthiessen gives his results for the resistance of copper at 0°. The observations were, however, made mostly at a temperature of 18° or 20°, and reduced to 0° by the use of a temperature co-efficient. So that the value at 18° found from that at 0° by the same co-efficient will probably represent the result of Matthiessen's work more accurately than the one he gives himself. Various other points of importance are discussed in Mr. Fitzpatrick's appendix. He hopes to be able to give the results for some copper prepared by chemical means by Mr. Skinner and himself. He has also made a number of measurements on silver, but these are not yet complete.

Dr. Muirhead and the Secretary have both been working independently at the construction and measurement of a standard air condenser.

Two such condensers have been made for the Committee by the Cambridge Scientific Instrument Company, on a plan suggested by Dr. Muirhead, and mentioned in the last Report. The capacity of each of these is about ·02 microfarad. Some slight alterations are required to one of these, the other is completely satisfactory. Its capacity has been repeatedly found, and remains constant to at least within 1 in 2,000, which is about the limit of accuracy attained. Its insulation resistance is good, the loss by leakage being about 1 in

1,000 of the total charge per 1 minute. It has been found possible to compare readily with this standard various mica condensers having capacities of 1, ·5, ·1, and ·05 microfarad. The accuracy of these determinations is about 1 in 2,000. A full account of the construction of the condensers, and of the method of making the various tests, is given in an appendix by the Secretary, while Dr. Muirhead has contributed some notes on his own condensers and tests.

Another appendix contains an account of a very careful and interesting comparison between the standard mercury thermometers of the Association and a platinum resistance thermometer constructed by Mr. E. H. Griffiths. The resistance thermometer was graduated by means of Regnault's numbers for the vapour pressure of water at various temperatures between 0 and 100.

The curve of corrections obtained in this way is exactly parallel to that given by the Kew comparisons; there is throughout the range a constant difference of 0·02 between them. This amount is within the limits of error on the mercury thermometer.

The question of the best value to adopt for the dimensions of a mercury column having a resistance of one ohm has been raised by some members of the Committee during the year. There is no doubt that the column of 106 centimetres adopted by the Paris Conference in 1884 is too short.

After a discussion of the results of the most recent observations, the following resolutions were adopted by the Committee:—

(1) The Committee recommend for adoption as a standard of resistance sufficiently near to the absolute ohm for practical purposes the resistance of a column of mercury 106·3 c.m. in length 1 square mm. in section at a temperature of 0° C.

(2) That for the purpose of issuing practical standards of resistance the number ·9866 be adopted as the ratio of the B.A. unit to the ohm.

Thus the new unit may be obtained from the B.A. unit by increasing it in the ratio ·9866 to unity, or, to put it differently, the specific resistance of mercury in B.A. units is taken as  $·9535 \times 10^{-4}$ , and the length of a column of mercury which has a resistance of one B.A. unit as 104·97 c.m. The specific resistance of mercury in ohms is  $·9407 \times 10^{-4}$ .

In conclusion the Committee wish to ask for reappointment to enable them to continue the work of constructing and issuing standard instruments. Of the grant of £50 made at Newcastle only £12 17s. has been drawn. In order to check any further change in the values of the B.A. units, and to render it less necessary to employ the original standards in all the comparisons which are made, it is desirable that the Committee should possess three or four copies of the B.A. unit; while, to enable comparisons to be made between the new air condensers and condensers of capacity compatible with a microfarad, a resistance box going up to several hundred thousand ohms is required.

The Committee are of opinion that they should be in a position to purchase these resistances; they therefore recommend that they be reappointed with a grant of £100, that Professor Carey Foster be the Chairman, and Mr. R. T. Glazebrook Secretary.

LIQUID INSULATION FOR UNDERGROUND  
CONDUCTORS.

By DAVID BROOKS.

THE first work on this system for practical purposes was laid for the English Post Office in 1880, along the South Western Railway between Waterloo Station and Clapham Junction.

It consisted in boiling cotton covered conductors in paraffin oil and drawing them into  $1\frac{1}{4}$  inch diameter iron pipe and afterwards filling the pipe with oil. There were 40 conductors of No. 18 B.W. gauge. Reservoirs were placed at elevated positions at Clapham and Waterloo to supply the loss of oil from leakage. The oil used was the ordinary petroleum fluid. The only difficulty experienced was from leakage through the joints of the pipe. This was remedied by the introduction of a heavy rosin oil of the consistency of the thicker grades of molasses. It has been working without interruption for the past ten years.

An improved method was patented February 1st, 1887. In the spring of that year 53 conductors were laid along the Pennsylvania Railroad, between the Broad Street Station and 32nd Street, in Philadelphia, a distance of one and one-third miles. Instead of the ordinary sockets, a T-joint is used where the insulation is introduced through a plug hole, which occurs at every length of pipe, or about 20 feet apart.

The insulation now used is almost a solid, at a temperature of  $32^{\circ}$  Fah., but as the temperature rises it becomes more liquid, and, being sufficiently heated in a caldron, is turned in at the T-joints. No stand pipe or reservoir is used.

The advantages of this insulation are :—

1. It is heavier than water and is not penetrated by it.
2. Always being liquid it does not crack, or contain small fissures for the admission of dampness.
3. It is not easily punctured by atmospheric electricity or currents of high voltage.
4. The insulation expands and contracts by every change of temperature, and thereby prevents the current centering upon any weak portion and developing a fault, as is often done in other kinds.

Other advantages of the system are :—

1. *Mechanical Strength.*—The wrought iron pipe is proof against penetration or injury by workmen's tools in street repairing.
2. *Cheapness.*—Iron pipe has five times the capacity of lead pipe of equal cost per foot, without making allowance for its greater strength and durability.
3. It is often said of conduits as compared with this system, that there are extra ducts for an increase of conductors when necessary. If the total cost of any conduit, including manholes, is divided by the number of ducts, the cost per foot is ascertained. Each duct of itself costs twice as much as the total cost by the liquid system, using all the conductors that the duct is capable of containing.
4. Conductors can be looped out of the pipe at any desired point to street lamps or for house-to-house purposes, by simply unscrewing a plug and inserting a smaller pipe, very much as gas or water is introduced.

When the cable was laid on the Pennsylvania Railroad, they had use for only 25 conductors, which left 28 idle. Since then, increase of business has brought five more into use. Provision was made for an increase. Extra conductors can be drawn into the pipe when the cable is laid, much cheaper than providing a place for them, as is done in the conduit system.

In the preceding article regarding conduits, the objections made to them are entirely obviated by the use of this system, inasmuch as the insulation is hermetically sealed from the effects of damp air and gases.

The cable laid at Gloucester is now working with a potential of 3,000 volts, alternating between conductors which are in the same pipe. It has 22 terminals exposed to the weather, and the insulation, making allowance for temperature, is as high as when first laid.

## NOTES.

**Electric Lighting in Berlin.**—Some notion may be arrived at of the extension of electric lighting systems in Berlin from the following figures :—

August of ...	1885	1886	1887	1888	1889
Ampères ...	1,462	5,875	7,827	13,290	22,000

**The Electric Light in Libraries.**—At the meeting of the Library Association of the United Kingdom held last week at Reading, Mr. W. H. Greenhough, the librarian at Reading, in a paper on "The Ventilating, Heating and Lighting of Libraries," drew attention to the evil effects of gas used in reading rooms. There is great need of improvement in most reading rooms with which we are acquainted. Too often, they are pleasant places rendered dangerous by the hot, stifling air. A large quantity of light must be supplied, and, consequently, gas brackets are placed in every accessible corner. We imagine that nowhere are the deleterious effects of gas felt more than in reading rooms. As to libraries it is a most important matter for those responsible for books to see that the wear and tear of their treasury is mitigated, and by using the electric light, bindings would be kept in good condition for an infinitely longer period than would be the case under a gaseous régime.

**Lighting of Reading Library.**—The Reading Library Committee has entered into a contract with the Electric Light Company specifying that the sum of £80 per annum should be paid for the supply of the current to the eight arc lamps to be used in the library and reading rooms, for providing the necessary carbons, and for keeping the lamps in order. The total illuminating power at the library is to be equal to 4,320 candles. The cost of gas formerly consumed in the library was £79 odd, while the total illuminating power was equal to some 1,360 candles. The result of the experience gained at Reading showed that, excellent though the electric lighting method was, yet, owing to the flickering and occasional failure of a lamp to light from one cause or another, it could by no means be said to be perfect.

**Electric Headlights on Locomotives.**—Electric headlights will be used in future on all passenger trains of the Louisville, New Albany and Chicago Road Railway.

**Electric Lighting in Havana.**—Reports to hand show that electric lighting is progressing rapidly. Some two years ago a local company was formed to work on the Westinghouse system. An apparatus, consisting of two 750 alternate current dynamos, was at once installed at the new central station; but before the wiring had been completed, so numerous were the demands for the supply of light, that the company immediately telegraphed to the United States for an alternating current plant for a capacity of 3,000 incandescent lights. Since this was erected the company have done good business and the demand will soon again exceed the supply. The Westinghouse Company is preparing further plant for shipment.

**Electric Lighting in Madrid.**—The Electricity Supply Company for Spain, acting under a concession from the local authorities, has recently erected a central station in Madrid, and houses at a distance of two miles from the works are being satisfactorily lighted. The cost of the station is £80,000, and the electricity is distributed by underground mains. The station is on the same lines as those proposed for Leeds by the Yorkshire House-to-House Electricity Company, being similar to the one erected by that company's engineers at Kensington.

**Light at the Gold Coast.**—The electric light is being used at the Gold Coast to assist the Apolite Company's quartz crushing operations. The installation comprises 15 arc lamps.

**Continental Lighting.**—The Railway Station and Post Office at Ulm will be lit by electricity after December 1st next. At Florence the municipal authorities are in treaty with the International Electricitäts Gesellschaft of Vienna for the establishment of an electric central station outside the city on the Ganz system for 10,000 lamps.

**Electric Lighting at Tiverton.**—At the last meeting of the Tiverton Town Council, it was resolved to appoint a committee to take into consideration the best means of carrying into operation the powers conferred upon the council by the Tiverton Electric Lighting Order, 1890. It was mentioned by Mr. Grason that the electric light would be cheaper than gas.

**Electric Lighting at Weybridge.**—An installation of 170 lamps has been made at Brooklands, Weybridge, Surrey. The engine-house is situated about a quarter of a mile from the mansion. The plant consists of a new 10 H.P. Marshall's locomotive boiler, fed by a Worthington pump, supplying, at 80 lbs. pressure, an old form of horizontal steam engine made by Hayward and Tyler, hitherto and still used to drive a circular saw. At night the engine is employed to drive a shunt wound dynamo, by Mackie, giving a current of 60 am-pères at a tension of 150 volts. The current is conveyed to the house by underground lead-covered cables, protected by glazed pipes with cemented joints. The installation has proved in every way a success.

**Personal.**—Mr. A. J. Howes is about to set out for Cairo, to undertake the erection of an electric installation at the Mena Hotel, Cairo.

**Fire.**—We are desired by Messrs. Cathcart and Peto to state that the recent fire at their Hatton Garden works will in no way interfere with their business.

**Water Power for an Electric Light Station.**—We have, on a former occasion, referred to the projected central station at Innsbruck, in Austria, and we are now in a position to give a detailed account of the work, taking the figures from a lecture by Director Geyer, of Augsburg. The design and construction of this installation is that of Messrs. Ganz & Co., of Buda-Pest. There is a waterfall at Muehlau, near Innsbruck, capable of furnishing a maximum of 600 H.P. The fall is 117 metres, giving a pressure upon the turbines of about 11.5 atmospheres. The water is led through pipes, 350 millimetres in diameter, to a pair of vertical turbines of 160 H.P. each. These turbines run at 250 revolutions per minute, and are coupled, direct, to two alternators, each capable of producing 40 am-pères with 2,000 volts. There are two exciters running at 700 revolutions per minute, giving 60 am-pères and 110 volts. The present capacity is 2,000 lamps of 16 C.P. each. The high tension current is carried on overhead conductors (eight mm. diameter) to a distance of about four kilometres till it reaches the outskirts of the town of Innsbruck; from there the current is distributed through a concentric main 5.86 kilometres in length. Until recently, the distribution of current has been as follows:—

207 incandescent lamps, each 10 C.P., taking...	39 watts.
510 " " " 16 " "	56 "
79 " " " 32 " "	112 "
1 " " " 50 " "	195 "
1 " " " 100 " "	390 "
3 arc lamps ... ..	each 800 "
1 electric motor of 5 H.P.	
1 " " 10 "	
Total, 51,466 watts.	

The minimum consumption was 8,000 watts, and the maximum at any time 40,000 watts. The building of this central station is high up on a hill commanding a beautiful view, and it has been constructed of stones found in neighbouring quarries. For the purpose of transporting the machinery to the spot, special roads had to be cut, involving a good deal of labour. The entire work—buildings and installation—has been carried out in excellent style.

**Electric Fire Accident in Paris.**—Parisians and others who happened to be on the Boulevard des Capucines on Thursday evening, the 18th inst., were considerably startled by the sudden extinction of the electric lights, and the issuing of dense clouds of smoke from an opening in the roadway in front of one of the lamps. It appears that the underground system of the Compagnie Popp had taken fire at the part between the Rue Danon and the Rue des Capucines. This gave rise to some groundless apprehension of an explosion on the part of the public. The damage was repaired in a couple of hours, during which time the neighbourhood was in complete obscurity, to the great inconvenience of traffic.

**Cable Interruption.**—The French Government cable between Soussa and Sfax, on the coast of Tunis, has been broken. This cable was laid in 1882, and, considering the nature of the bottom, and the dangers which cables along this coast are subjected to at the hands of sponge fishers, it may be regarded as having lasted well.

**Lyons Tramway.**—Experiments have been successfully carried out on the Lyons Monplaisir-la-Plaine Tramway in adapting electrical propulsion to the ordinary tramcars. One of these cars was fitted with electric motors worked from 56 accumulator cells. A speed of from 12 to 14 kilometres per hour was maintained during the double journey between Lyons and the station at Monplaisir. The accumulators were made by the firm of Alioth, and are able to supply from 8 to 9 H.P. for eight consecutive hours. The comfort of the passengers was greatly increased by the car being electrically lighted.

**A New Telephonic Experiment.**—An experiment with the telephone is to be made in Birmingham next Sunday. Transmitters will be set up in Christ Church, New Street, so that subscribers to the telephone, if they desire, can hear the service and the sermon at their private residences. The general manager of the company has been encouraged to make the trial by the success which attended a similar scheme initiated by him eight years ago at Bradford. At the end of the choir stalls, on the top of the lectern at the reading desk, and at the pulpit desk, small metal cased transmitters will be placed, and they will be so regulated that sound vibration will be taken up without requiring the voice to be directed immediately upon the plate of the transmitter.

**Electric Welding.**—The wire for covering the tube of the new 10-inch gun, now in course of construction for the United States, is being joined by the electric welding process.

**Westinghouse Strike.**—The strike of the *employés* of the Westinghouse Company at Pittsburg was terminated on September 3rd by the capitulation of the strikers, who requested their old places.

**The Chinese Telegraph Convention.**—In the petition presented by the English merchants resident in China, many complaints are made against the cable companies. According to their statements, they have not derived the advantage which was to be expected from the two separate lines of the Eastern Extension and the Great Northern of Copenhagen, because the two companies, since 1875, have been working in combination, and maintained a rate of 6s. a word between Hong Kong and Europe. They can only communicate with America through Europe. The Convention of 1887 between the Chinese Government and the cable companies is referred to in bitter terms; the Government were, under this agreement, compelled to charge the same rate over their land lines to Europe as the companies. They beg that the Convention may not be ratified by Her Majesty's Government.

**Ship Wiring.**—The New York *Times*, of September 5th, commenting on a threatened fire on board of the *Etruria*, during a then recent passage across the Atlantic, caused by a short circuit in the electric leads, takes the opportunity of comparing the English and American methods of ship wiring, unfavourably to the former system. The article states that all the first-class liners running between England and the United States are wired on the single-wire system, in which the hull of the ship is utilised as the return wire, this plan being the cheapest way yet devised, owing to the large saving in copper, and from the inexpensive manner in which the wires are slung up, as well as from the small number of fusible plugs usually employed. In contradistinction to the danger that is ever present in a ship wired in the English fashion, the American method is so exhaustively perfect in every detail, that it is almost a moral impossibility for any accident, by fire or shock, to occur. The leads are protected first by the insulation, then by a lead covering to prevent corrosion, and, finally, by a wooden casing, from all mechanical injury. Fusible plugs are provided for each lamp. The junction boxes and cut-out boxes used in the American system of marine work are equally complete and much superior to the English construction. The boxes are waterproof and almost hermetically sealed, supplied with stuffing boxes and water-tight covers. Nothing but the cheapness of the English system can account for its criminal employment on the finest steamers in the world. So much from the New York *Times*, whose article reads like an excerpt from some glowing and gushing prospectus, the truth of which, at least in its practical development, may possibly be open to some doubt. In this doubt the gentleman who sent us the article joins, and is amazed at the presumptive tone in which it is couched, and further states, from a five years' experience, he believes that nearly all the wiring on the American side is simply slung up in the roughest manner. However true these statements may be, it is not improbable that the competition in securing contracts for ship lighting in England and Scotland does lead to inferior work and material being used on board ship, and, in the absence of efficient and thorough outside control in the selection of material, and of their proper disposition during the progress of the work, may eventually result in some serious disaster at sea.

**City and Guilds of London Institute.**—Prof. Ayrton's special course for *outside* students will be given every Monday and Wednesday, at Exhibition Road, at 3 p.m., commencing Monday, October 6th. The subject will be "The Construction of Direct and Alternate Current Dynamos and Motors, and the Methods of Testing their Power and Efficiency."

**Obituary.**—M. Gavarret, author of a "Traité d'Electricité," published in 1857, and of a "Traité de Télégraphie Electrique," published in 1849, and also of a treatise upon the electro-physiological researches of Galvani, published in the *Annales de Chimie et Physique*, has just died, aged 81.

**Electric Hair Curler.**—By the aid of this useful and beautiful invention, the hair, beard, or moustache can be curled in any style in one minute. It produces any form desired by ladies wearing their hair in the fashionable "loose and fluffy mode." Thus runs the wrapper of an article which has been submitted to our notice. We are told to hold the curler in the gas a few seconds, very little heat being required, on account of its highly magnetic qualities. Unfortunately our editorial hair, when worn, is neither "loose nor fluffy," and we must leave the testing of the instrument to others.

**The Story of Laying a Cable.**—Mr. Herbert Laws Webb, New York, will contribute to the October number of *Scribner's* an article entitled, "With a Cable Expedition," descriptive of the process of cable laying, and the life on board ship.

**French Telephones.**—M. Selves intends to reorganise the State service entirely. He proposes to suppress five of the eleven intermediary offices and establish one central office in their place. This central office will be occupied with the service of 6,000 of the total 8,800 subscribers, and will be located near to the Hôtel des Postes, at a cost of 800,000 francs, exclusive of building expenses.

**Jamaica Industrial and Manufacturing Exhibition.**—The contract for lighting this exhibition has been secured by Messrs. Nicholson and Jennings, of 7, Westminster Chambers, Victoria Street, S.W., who have tendered in accordance with the specification prepared by Mr. Kenneth Mackenzie, of 15, Great George Street, Westminster, who is acting as consulting engineer to the commissioners. This exhibition will be opened in January next, and will remain so for at least three months; being the first exhibition held in that part of the world, it is naturally creating considerable attention. The contract includes motive power and plant for an equivalent of 70 arc lamps and 650 glow lamps, or equal to an electrical output of 74,000 watts; and, since the buildings which are being erected will be spacious and of an elegant design, the effect, both in the interior of the exhibition as well as the ornamental grounds will be very striking. The contract also includes two electric motors of 20 H.P. each, for running some of the counter-shafting supplying power to exhibitors. The West Indies are at present, certainly as far as regards the enterprise of English electrical contractors, altogether untouched, since the greater part of whatever has been done there up to now has been supplied from the United States; and it is thought that a considerable impetus will be given to trade by the fact of this exhibition being organised by the government of the largest English colony there. We understand that Mr. Mackenzie will be glad to give information and particulars to any electrical firms who might feel inclined to utilise the advantages which this exhibition will offer for opening up a trade in the West Indian islands and Central America.

**The Electric Light on the German Railways.**—In Germany, on the railway lines on the banks of the Rhine, the electric light has been employed for some years with success. The *Voss Gazette* now informs us that the directors of the Prussian railways are about to light, as a trial, a certain number of carriages with incandescent lamps. Five of these lamps will be installed in each carriage. The intensity of the light can be regulated by the passengers as they wish.

**The African Telegraph Service.**—The first telegram direct from the German-African coast arrived last week in Hamburg. It was addressed by Serva Hadji to Captain Baron Von Gravenreuth, and ran as follows:—"Lauterberg from Bagamoyo. Gravenreuth Salaam. Serva Hadji. Two members of the telegraph staff have just left Marseilles for Dar-es-Salaam with a view to organising the telegraph service there."

**Dry Batteries.**—The following directions, with reference to a dry battery manufactured by an American firm, suggests that the name *dry* has been given by an inhabitant of the Emerald Isle. "To fully charge battery remove the cover and pour in slowly through the holes in the top *one gill of pure water*."

**Telephone and the Benwell Murder.**—So great is the interest in this case, that telephone wires have been connected from the Court to a neighbouring hotel. Transmitters are placed near the heads of the counsel, thus enabling the trial to be heard with distinctness. The wires, which almost obstruct the view, called forth a protest from the judge.

**Double-Cylinder Phonograph.**—An improved phonograph has been invented by an American which takes a record on two cylinders simultaneously.

**Electric Cars in Leeds.**—The Thomson-Houston Company has offered to equip a section of line in Leeds with electric cars, and pay a nominal rent of 100 guineas a year. If, on the expiration of two years, the Corporation decides to adopt electricity as the motive power upon the tramways, it will be able to take over the concern from the American company at a valuation. This will be no doubt favourably considered by the Highways Committee.

**The Electro-Harmonic Society.**—The concerts of this season—the fifth—will be six in number, and are announced to take place on the evenings of the following dates:—Friday, October 3rd, 1890, Smoking Concert; Friday, November 7th, 1890, Smoking Concert; Monday, December 8th, 1890, Ladies' Night; Friday, January 30th, 1891, Smoking Concert; Friday, February 27th, 1891, Ladies' Night; Friday, April 10th, 1891, Smoking Concert. At the first of the series Messrs. A. Thompson, W. G. Forington, W. Nicholl and Frederick Upton will perform, whilst the instrumental portion of the programme will be in the hands of Messrs. T. E. Gatehouse and Alfred Izard.

**Wade's Patent Arc Lamp Tablets.**—With the view of utilising the strong light of the arc lamp for advertising purposes, transparent tablets are now manufactured, lettered in various colours, and so made as to fit any type of lamp. Some are constructed of two bent

panels joined at the ends, forming an oval enclosure for the lamp, and others of four panels, forming a square enclosure for the lamp. They do not diminish the light, and are effective both by day and night. They are supplied by the Woodhouse and Rawson United Company, Limited.

**Telephone Induction Coils.**—The article on Telephone Induction Coils, which we give in our present issue, opens up an interesting subject. Those who have experimented largely with different forms and sizes of coils for telephonic purposes can hardly fail to have been struck with the extraordinarily small difference which is found to exist in the working qualities of the different types—long coils, short coils, coils of small diameter, coils of large diameter, coils with large cores, and coils with small cores all seem to give very nearly similar results; even the gauge of wire used in the primary and in the secondary makes surprisingly little difference. The cause of all this has, we believe, never been explained, nor attempted to be explained. Great hopes were entertained that coils on the transformer principle would give remarkably good results, but quite the contrary turned out to be the case, and the reason is now evident if it were not so before.

**Electric Lighting in Chelsea.**—In the report of the surveyor to the parish, we find the following remarks: There are in Chelsea actually using the electric light, about 139 houses supplied as follows, viz.:—

Chelsea Electricity Supply Co. ..	113 houses.
Cadogan Electric Light Co. ...	25 "
London Electric Supply Corporation ...	1 "
139	

It should be borne in mind that the desire for electric light in Chelsea is not, as in most parishes, an outcome of the electric lighting mania of 1882, but dates from some four years prior to that period, and that what at first sight looks like slow progress, is really the natural growth of an important industry which, in each stage of its advancement, bears marks of the careful attention bestowed upon it by the Chelsea vestry.

## NEW COMPANIES REGISTREED.

**Electrical Inventions Company, Limited.**—Capital, £35,000 in £1 shares. Objects: To acquire, work, develop and deal with patents of electrical inventions and improvements, and of electrical instruments and apparatus of every description, whether patented or not. Signatories (with 1 share each): W. Dare, 15, Stansfield Road, Stockwell; S. B. Witherby, 5, Holly Villas, Highgate; A. Good and A. W. Good, 57, Moor-gate Street; R. Radermacher, 16, Golborne Road, W.; Bruce Kedge, 29, Morrison Road, S.W.; C. Jellicoe, 74, Godolphin Road, Shepherd's Bush. The signatories are to appoint the first directors; qualification for subsequent directors, £190 in shares; the company in general meeting will appoint remuneration. Registered 18th inst. by A. W. Rixon, 10, Austin Friars.

**J. E. H. Gordon and Company, Limited.**—Capital, £50,000 in £10 shares. Objects: To acquire as a going concern the business of electrical engineer carried on by J. E. H. Gordon, M.Inst.C.E., and to construct, manufacture, supply, and maintain electric light machinery and apparatus. Signatories (with 1 share each): \*J. E. H. Gordon and Mrs. Gordon, 1, Queen's Gate Gardens; \*W. J. Rivington and Mrs. Rivington, 21, Gledhow Gardens, South Kensington; Mrs. E. C. Gordon and Miss E. C. Gordon, Hornlow Cottage, Campden Hill, W.; Hy. Sinclair, 11, Pall Mall. The signatories denoted by an asterisk are the first directors; qualification, 200 shares. Registered 19th inst. by Messrs. Mann and Taylor, 109, New Oxford Street.

**Combination Telephone and Electrical Engineering Company, Limited.**—Capital, £20,000, in £1 shares. Objects: To acquire and work the letters patent, Nos. 5,008 and 7,553, both of 1890, relating to telephones, and to take over as a going concern the business of Charles James Grist, carried on at 43, Sydney Street, Oxford Road, Manchester. To carry on the business of a telephone, telegraph and electric light, heat and power supply company. Signatories (with one share each): A. Lewis, 204, Elgin Avenue, W.; T. J. Cook, 4, Bovill Road, Forest Hill; H. C. Fowler, St. Paul's Road, Tottenham; H. T. Raw, 140, Birchanger Road, Woodside, S.E.; S. N. Smith, 68, Holmes Road, Kentish Town; T. E. Halford, 33, Priory Road, Bedford Park; C. Howard, 59, Lennox Road, Walthamstow. Messrs. C. J. Grist and E. Frank Fartado are appointed managing directors, each at a salary of £300 per annum. The ordinary directors will be entitled to £75 per annum each, with £45 additional to the chairman. Qualification, 50 shares. Registered, 19th inst., by Ernest Salaman, 65 and 66, Chancery Lane. Registered office, 35, New Broad Street.

**J. H. Holden and Company, Limited.**—Capital, £1,000, in £1 shares. Objects: To carry on business as cotton, wool, flax, hemp, jute and yarn merchants. To generate, use, let, or supply electric, gas, steam, or other power. Signatories (with one share each): J. H. Holden, Tonge; P. Crook, Bolton; W. Schmid, Bolton; F. T. Hilton, Bolton; Miss A. Nuttall, Bolton; P. Kirkham, Preston; Mrs. M. Holden, Bolton; all in

Lancashire. Registered, 19th inst., without special articles, by R. Jordan, 120, Chancery Lane. Office, Bradshawgate, Bolton, Lancaster.

## OFFICIAL RETURNS OF ELECTRICAL COMPANIES.

**British Electric Propulsion and Traction Company, Limited.**—The annual return of this company, made up to the 18th inst., was filed on the same day. The nominal capital is £5,000, in £1 shares. 3,241 shares have been issued, 3,184 being considered fully paid. Upon 57 shares the full amount has been called and paid.

**Woodhouse and Rawson United, Limited.**—An agreement of 3rd inst. (filed 15th inst.) is supplemental to an agreement of 15th July entered into with Woodhouse and Rawson Electric Manufacturing Company, Limited (called the vendor company). The sale and purchase of the property referred to in the principal agreement has not yet been completed, for divers reasons, principally legal questions between the vendor company and other parties as to certain important assets. Until settlement thereof, it is deemed desirable that no steps should be taken for the liquidation of the company, and it is agreed to modify the terms of the principal agreement. It is therefore agreed that the purchase money payable shall be apportioned as follows:—

The plant, other than incandescent lamp plant ...	£5,250
The stock, other than stock of incandescent lamps ...	11,750
Patents and licences ...	11,000
Goodwill ...	3,500
Stock of incandescent lamps, and incandescent lamp plant ...	500
	<u>£32,000</u>

The sum of £23,000 is payable in ordinary shares and in fully paid shares.

An agreement of 3rd September (registered 15th inst.) with the Woodhouse and Rawson Electrical Supply Company of Great Britain, Limited, is also supplemental to an agreement of 15th July. For similar reasons the purchase consideration is modified until the settlement of the question involved, to £15,000, of which £12,500 is payable in fully paid shares.

## CITY NOTES, REPORTS, MEETINGS, &c.

### The Direct Spanish Telegraph Company, Limited.

THE report of the directors for the half-year ended 30th June, 1890, to be presented at the general meeting of shareholders, to be held on Tuesday, September 30th, 1890, states that the accounts show, after providing for debenture interest, a balance to the credit of profit and loss of £7,199 17s. 2d. The traffic receipts have again been satisfactory, and show an increase of £2,057 1s. 8d. as compared with the corresponding half-year of 1889. The working expenses are £391 0s. 8d. in excess of those for the corresponding period of last year. The company's cables, and the land-lines in connection with them, have continued in good working order throughout the half-year. The company was represented at the International Telegraph Conference held at Paris in May last, and had, as well as other telegraph companies and administrations, to submit to reductions of tariff which will affect the company's revenue to some extent. These reductions do not come into force until the 1st July, 1891.

An extraordinary general meeting will take place immediately after the ordinary general meeting, in accordance with the following resolution which was unanimously adopted by the shareholders at the last ordinary general meeting.

"That in the opinion of this meeting the directors' remuneration should be now increased beyond the sum of £400 per annum, and that in view of their declared intention not to avail themselves of their rights under the 71st of the company's articles of association as it now stands, the directors be, and are hereby requested, to give notice of a special resolution being brought forward at the next half-yearly meeting for altering article 71, so as to increase their remuneration to £600, or otherwise, as may from time to time be voted in general meeting."

Of the balance of profit and loss, £2,500 have been put to the reserve fund, which now amounts to £20,258 6s. 6d., leaving a

balance of £4,699 17s. 2d. Out of this amount the directors recommend the payment of the dividend at the rate of 10 per cent. per annum on the preference shares, and a dividend at the rate of 6 per cent. per annum (free of income tax) on the ordinary shares. This will admit of a sum of £1,685 12s. 9d. being carried to the "contingencies account," which the directors consider it indispensable to maintain, in view of fluctuations of traffic, &c., the reserve fund applying solely to the renewal of the cables.

The dividend warrants will be issued on the 1st October, 1890.

### General Electric Power and Traction Company, Limited.

THE statutory meeting of this company was held at Winchester House, on Tuesday, Viscount Bury presiding.

The Chairman said his task was a purely formal one, the meeting being held, in pursuance of statute, for the purpose of giving the shareholders an opportunity of satisfying themselves, by personal communication with the board, at a short period after commencement of operations, that all the requirements of the various Acts have been complied with, and that everything is in regular and due order. He was happy to say that the affairs of the company were in complete order. No accounts had been issued, because it would be entirely premature to talk about what had been done or what was going to be done in the immediate future. A time would shortly arrive when the directors would have something to say upon those subjects. All he could tell them was that the company, which began as a going concern, was going on in a satisfactory manner. The directors had been constantly and energetically occupied with the various details of the factory, the mining branch, and the launches. The company's electrical cars were running in a satisfactory manner. The electrical works were under the management of Mr. A. T. Snell, who was well known as a most efficient and successful engineer, and who had occupied a high position under Mr. Immisch, at the "Immisch" works. They were very satisfactorily developing the mining plant, and had received very considerable orders in that department. Very satisfactory enquiries had been received from the various departments of electric traction, especially those devoted to tramways. In fact, the company had a future before it which, as he was not addicted to strong language, he would not call brilliant, but which he would call satisfactory, to his colleagues and himself.

A Shareholder would like to know to what extent shares had been taken?

The Chairman thought it was not a strictly regular question; it was certainly no part of the business of the present meeting. But, while anxious to keep within the usual routine, he saw no objection to saying that, with the exception of £8,000, the whole of the shares, ordinary and preference, had been allotted; and the whole proceeds of the preference shares would be devoted to the working of the company.

The proceedings then terminated.

### Elmore's Wire Manufacturing Company, Limited.

THE Stock Exchange has appointed to-day a special settling day for Elmore's Wire Manufacturing Company, Limited, shares Nos. 1 to 67,358, and has ordered the unmentioned securities to be quoted:—Preference shares, Nos. 1 to 50,000; Elmore's Patent Copper, vendors' shares, Nos. 1 to 23,300; Elmore's Wire Manufacturing Company, Limited, shares Nos. 1 to 67,358.

**Elmore's Copper Companies.**—The first batch of letters of allotment in Elmore's French Patent Copper Depositing Company, Limited, has been posted. "We," says a financial paper, "are informed that the issue has been subscribed nearly four times over, the actual number of shares applied for being 253,951." The shares are quoted 1½ to 1¼ prem. An Austrian Elmore's Copper Company is to be brought out in a few days.

**Stock Exchange Settlements.**—Application has been made to the Stock Exchange to appoint a settling day, and to grant a quotation to the International Okonite Company, Limited, preference shares, Nos. 5,667 to 17,000; ordinary shares, Nos. 22,667 to 34,000; and £517,000 6 per cent. debentures. *Woodhouse and Rawson United, Limited.*—Ordinary shares Nos. 1 to 31,416, and preference shares Nos. 40,001 to 54,285.

**Globe Telegraph and Trust Company, Limited.**—The directors have declared an interim dividend of 1s. 9d. per share, payable on the 18th proximo.

**Eastern Extension, Australasia, and China Telegraph Company, Limited.**—Interim dividend for June quarter of 2s. 6d. per share, payable on the 15th prox., has been declared by the directors.

## TRAFFIC RECEIPTS.

The Brazilian Submarine Telegraph Company, Limited. The traffic receipts for the week ending September 19th, were £4,840.

The Western and Brazilian Telegraph Company, Limited. The receipts for the week ending September 19th, after deducting the fifth of the gross receipts payable to the London Platino-Brazilian Telegraph Company, Limited, were £3,627.

# THE ELECTRO-MAGNET.\*

By Prof. SILVANUS P. THOMPSON, D.Sc., B.A., M.I.E.E.

(Continued from page 332.)

IN the next number of "Silliman's Journal" (April, 1831), Prof. Henry gave "an account of a large electro-magnet, made for the laboratory of Yale College." The core of the armature weighed 59½ lbs., it was forged under Henry's own direction, and wound by Dr. Ten Eyck. This magnet, wound with 26 strands of copper bell wire of total length of 728 feet, and excited by two cells which exposed nearly 4½ square feet of surface, readily supported on its armature, which weighed 23 lbs., a load of 2,063 lbs.

Writing in 1867 of his earlier experiments, Henry speaks † thus of his ideas respecting the use of additional coils on the magnet and the increase of battery power:—

"To test these principles on a larger scale, the experimental magnet was constructed, which is shown in fig. 6. In this a

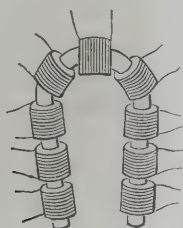

FIG. 6.—HENRY'S EXPERIMENTAL ELECTRO-MAGNET.

number of compound helices was placed on the same bar, their ends left projecting, and so numbered that they could all be united into one long helix, or variously combined in sets of lesser length.

"From a series of experiments with this and other magnets, it was proved that in order to produce the greatest amount of magnetism from a battery of a single cup a number of helices is required; but when a compound battery is used, then one long wire must be employed, making many turns around the iron, the length of wire, and consequently the number of turns, being commensurate with the projectile power of the battery.

"In describing the results of my experiments, the terms 'intensity' and 'quantity' magnets were introduced to avoid circumlocution, and were intended to be used merely in a technical sense. By the intensity magnet I designated a piece of soft iron, so surrounded with wire that its magnetic power could be called into operation by an intensity battery; and by a quantity magnet, a piece of iron so surrounded by a number of separate coils, that its magnetism could be fully developed by a quantity battery.

"I was the first to point out this connection of the two kinds of the battery with the two forms of the magnet; in my paper, in 'Silliman's Journal,' January, 1831, and clearly to state that when magnetism was to be developed by means of a compound battery, one long coil must be employed, and when the maximum effect was to be produced by a single battery, a number of single strands should be used. . . . Neither the electro-magnet of Sturgeon nor any electro-magnet ever made previous to my investigations was applicable to transmitting power to a distance. . . . The electro-magnet made by Sturgeon, and copied by Dana, of New York, was an imperfect quantity magnet, the feeble power of which was developed by a single battery."

Finally, Henry ‡ sums up his own position as follows:—

"1. Previous to my investigations, the means of developing magnetism in soft iron were imperfectly understood, and the electro-magnet which then existed was inapplicable to transmissions of power to a distance.

"2. I was the first to prove by actual experiment that in order to develop magnetic power at a distance, a galvanic battery of 'intensity' must be employed to project the current through the long conductor, and that a magnet surrounded by many turns of one long wire must be used to receive this current.

"3. I was the first to actually magnetise a piece of iron at a distance, and to call attention to the fact of the applicability of my experiments to the telegraph.

"4. I was the first to actually sound a bell at a distance by means of the electro-magnet.

"5. The principles I have developed were applied by Dr. Gale to render Morse's machine effective at a distance."

Though Henry's researches were published in 1831, they were for some years almost unknown in Europe. Until April, 1837, when Henry himself visited Wheatstone at his laboratory at King's College, the latter did not know how to construct an electro-magnet that could be worked through a long wire circuit. Cooke, who became the coadjutor of Wheatstone, had originally

come to him to consult him,\* in February, 1837, about his telegraph and alarm, the electro-magnets of which, though they worked well on short circuits, refused to work when placed in circuit with even a single mile of wire. Wheatstone's own account† of the matter is extremely explicit:—"Relying on my former experience, I at once told Mr. Cooke that his plan would not and could not act as a telegraph, because sufficient attractive power could not be imparted to an electro-magnet interposed in a long circuit; and to convince him of the truth of this assertion, I invited him to King's College to see the repetition of the experiments on which my conclusion was founded. He came, and after seeing a variety of voltaic magnets, which, even with powerful batteries, exhibited only slight adhesive attraction, he expressed his disappointment."

After Henry's visit to Wheatstone, the latter altered his tone. He had been using, *faute de mieux*, relay circuits to work the electro-magnets of his alarm in a short circuit with a local battery. "These short circuits," he writes, "have lost nearly all their importance, and are scarcely worth contending about since my discovery" (the italics are our own) "that electro-magnets may be so constructed as to produce the required effects by means of the direct current, even in very long circuits."‡

We pass on to the researches of the distinguished physicist of Manchester, whose decease we have lately had to deplore, Mr. J. P. Joule, who, fired by the work of Sturgeon, made most valuable contributions to the subject. Most of these were published either in Sturgeon's "Annals of Electricity," or in the "Proceedings of the Literary and Philosophical Society of Manchester," but their most accessible form is the republished volume issued five years ago by the Physical Society of London.

In his earliest investigations he was endeavouring to work out the details of an electric motor. The following is an extract from his own account ("Reprint of Scientific Papers," p. 7.):—

"In the further prosecution of my enquiries, I took six pieces of round bar iron of different diameters and lengths, also a hollow cylinder, ⅛th of an inch thick in the metal. These were bent in the U-form, so that the shortest distance between the poles of each was half an inch; each was then wound with 10 feet of covered copper wire, ⅛th of an inch in diameter. Their attractive powers under like currents for a straight steel magnet, 1½ inch long, suspended horizontally to the beam of a balance, were, at the distance of half an inch, as follows:—

	No. 1. Hollow.	No. 2. Solid.	No. 3. Solid.	No. 4. Solid.	No. 5. Solid.	No. 6. Solid.	No. 7. Solid.
Length round the bend in inches. . . . .	6	5½	2½	5½	2½	5½	2½
Diameter in inches . . .	½	½	½	¾	¾	¾	¾
Attraction for steel mag- net, in grains. . . . .	7.5	6.3	5.1	5.0	4.1	4.8	3.6
Weight lifted, in ounces	36	52	92	36	52	20	28

"A steel magnet gave an attractive power of 23 grains, while its lifting power was not greater than 60 ounces.

"The above results will not appear surprising if we consider, first, the resistance which iron presents to the induction of magnetism, and, second, how very much the induction is exalted by the completion of the magnetic circuit.

"Nothing can be more striking than the difference between the ratios of lifting to attractive power at a distance in the different magnets. Whilst the steel magnet attracts with a force of 23 grains and lifts 60 ounces, the electro-magnet No. 3 attracts with a force of only 5.1 grains, but lifts as much as 92 ounces.

"To make a good electro-magnet for lifting purposes:—1. Its iron, if of considerable bulk, should be compound, of good quality, and well annealed. 2. The bulk of the iron should bear a much greater ratio to its length than is generally the case. 3. The poles should be ground quite true, and fit flatly and accurately to the armature. 4. The armature should be equal in thickness to the iron of the magnet.

"In studying what form of electro-magnet is best for attraction from a distance, two things must be considered, viz., the length of the iron, and its sectional area.

"Now I have always found it disadvantageous to increase the length beyond what is needful for the winding of the covered wire."

These results were announced in March, 1839. In May of the same year Joule propounded a law of the mutual attraction of two electro-magnets as follows:—"The attractive force of two electro-magnets for one another is directly proportional to the square of the electric force to which the iron is exposed; or if  $E$  denote the electric current,  $w$  the length of wire, and  $m$  the magnetic attraction,  $m = E^2 w^2$ ." The discrepancies which he himself observed he rightly attributed to the iron becoming saturated magnetically. In March, 1840, he extended this same law to the lifting power of the horseshoe electro-magnet.

In August, 1840, he wrote to the "Annals of Electricity" on electro-magnetic forces, dealing chiefly with some special electro-magnets for traction. One of these possessed the form shown in

\* Cantor Lecture. Delivered before the Society of Arts, January 20th, 1890.

Fig. 7. Both the magnet and the iron keeper were furnished with eye-holes for the purpose of suspension and measurement of the force requisite to detach the keeper. Joule thus writes about the experiments \* :—

"I proceed now to describe my electro-magnets, which I constructed of very different sizes, in order to develop any curious circumstance which might present itself. A piece of cylindrical wrought iron, eight inches long, had a hole one inch in diameter, bored the whole length of its axis; one side was planed until the hole was exposed sufficiently to separate the thus formed poles one-third of an inch. Another piece of iron, also eight inches long, was then planed, and being secured with its face in contact with the other planed surface, the whole was turned into a cylinder eight inches long, three and three-quarter inches in exterior, and one inch interior diameter. The larger piece was then covered with calico and wound with four copper wires covered with silk, each 23 feet long, and  $\frac{1}{16}$ th of an inch in diameter—a quantity just sufficient to hide the exterior surface, and to fill the interior opened hole." . . . . . "The above is designated No. 1, and the rest are numbered in the order of their description.

"I made No. 2 of a bar of half-inch round iron 2·7 inches long. It was bent into an almost semi-circular shape, and then covered with seven feet of insulated copper wire  $\frac{1}{16}$ th of an inch thick. The poles are half an inch asunder, and the wire completely fills the space between them.

"A third electro-magnet was made of a piece of iron 0·7 inch long, 0·37 inch broad, and 0·15 inch thick. Its edges were reduced to such an extent that the transverse section was elliptical. It was bent into a semi-circular shape, and wound with 19 inches of silked copper wire,  $\frac{1}{16}$ th of an inch in diameter.

"To procure a still more extensive variety, I constructed what might, from its extreme minuteness, be termed an *elementary electro-magnet*. It is the smallest, I believe, ever made, consisting of a bit of iron wire  $\frac{1}{4}$  of an inch long, and  $\frac{1}{16}$ th of an inch in diameter. It was bent into the shape of a semi-circle, and was wound with three turns of *uninsulated* copper wire  $\frac{1}{16}$ th of an inch in thickness."

With these magnets experiments were made with various strengths of currents, the tractive forces being measured by an arrangement of levers. The results, briefly, are as follows :— Electro-magnet No. 1, the iron of which weighed 15 lbs., required a weight of 2,090 lbs. to detach the keeper. No. 2, the iron of which weighed 1,057 grains, required 49 lbs. to detach its armature. No. 3, the iron of which weighed 65·3 grains, supported a load of 12 lbs., or 1,286 times its own weight. No. 4, the weight of which was only half a grain, carried in one instance 1,417 grains, or 2,834 times its own weight.

"It required much patience to work with an arrangement so minute as this last; and it is probable that I might ultimately have obtained a larger figure than the above, which, however, exhibits a power proportioned to its weight far greater than any on record, and is eleven times that of the celebrated steel magnet which belonged to Sir Isaac Newton.

"It is well known that a steel magnet ought to have a much greater length than breadth or thickness; and Mr. Scoresby has found that when a large number of straight steel magnets are bundled together, the power of each when separated and examined is greatly deteriorated. All this is easily understood, and finds its cause in the attempt of each part of the system to induce upon the other part a contrary magnetism to its own. Still there is no reason why the principle should in all cases be extended from the steel to the electro-magnet, since in the latter case a great and commanding inductive power is brought into play to sustain what the former has to support by its own unassisted retentive property. All the preceding experiments support this position, and the following table gives proof of the obvious and necessary general consequence, the maximum power of the electro-magnet is directly proportional to its least transverse sectional area. The second column of the Table contains the least sectional area in square inches of the entire magnetic circuit. The maximum power in pounds avoirdupois is recorded in the third; and this, reduced to an inch square of sectional area, is given in the fourth column under the title of specific power."

TABLE I.

Description.	Least Sectional Area.	Maximum Power.	Specific Power.
My own electro-magnets	No. 1. . . . .	10	2090
	No. 2. . . . .	0·196	49
	No. 3. . . . .	0·0436	12
	No. 4. . . . .	0·0012	0 202
Mr. J. C. Nesbit's. Length round the curve, 3 feet; diameter of iron core, 2 $\frac{3}{4}$ in.; sectional area, 5·7 in.; do. of armature, 4·5 in.; weight of iron, about 50 lbs. . . . .	4·5	1428	317
Prof. Henry's. Length round the curve, 20 in.; section, 2 in. square; sharp edges rounded off; weight, 21 lbs. . . . .	3·94	750	190
Mr. Sturgeon's original. Length round the curve, about 1 ft.; diameter of the round bar, $\frac{1}{2}$ in. . . . .	0·196	50	255

\* "Scientific Papers," vol. i., p. 30.

"The above examples are, I think, sufficient to prove the rule I have advanced. No. 1 was probably not fully saturated; otherwise I have no doubt that its power per square inch would have approached 300. Also the specific power of No. 4 is small, because of the difficulty of making a good experiment with it."

These experiments were followed by some to ascertain the effect of the length of the iron of the magnet, which he considered, at least in those cases where the degree of magnetisation is considerably below the point of saturation, to offer a decidedly proportional resistance to magnetisation; a view the justice of which is now after 50 years amply confirmed.

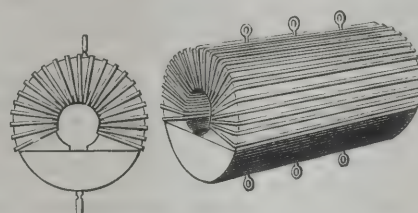

FIG. 7.—Joule's ELECTRO-MAGNET.

In November of the same year further experiments\* in the same direction were published. A tube of iron, spirally made and welded, was prepared, planed down as in the preceding case, and fitted to a similarly prepared armature. The hollow cylinder thus formed, shown in fig. 8, was 2 feet in length, its internal

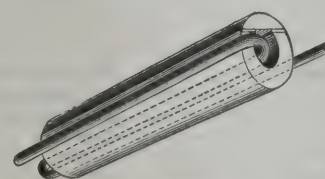

FIG. 8.—Joule's CYLINDRICAL ELECTRO-MAGNET.

diameter was 1·42 inch, its internal being 0·5 inch. The least sectional area was 10 $\frac{1}{2}$  square inches. The exciting coil consisted of a single copper rod, covered with tape, bent into a sort of S-shape. This was later replaced by a coil of 21 copper wires, each  $\frac{1}{16}$ th inch in diameter and 23 feet long, bound together by cotton tape. This magnet, excited by a battery of 16 of Sturgeon's cast-iron cells, each one foot square and one and a-half inch in interior width, arranged in a series of four, gave a lifting power of 2,775 lbs.

Joule's work was well worthy of the master from whom he had learned his first lesson in electro-magnetism. He showed his devotion not only by writing descriptions of them for Sturgeon's "Annals," but by exhibiting two of his electro-magnets at the Victoria Gallery of Practical Science, of which Sturgeon was director. Others, stimulated into activity by Joule's example, proposed new forms, amongst them being two Manchester gentlemen, Mr. Radford and Mr. Richard Roberts, the latter being a well-known engineer and inventor. Mr. Radford's electro-magnet consisted of a flat iron disc, with deep spiral grooves cut in its face, in which were laid the insulated copper wires. The armature consisted of a plain iron disc of similar size. This form is described in Vol. IV. of Sturgeons "Annals." Mr. Roberts's form

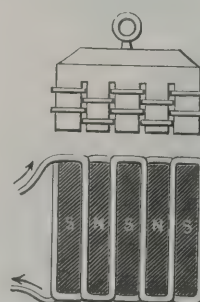

FIG. 9.—ROBERTS'S ELECTRO-MAGNET.

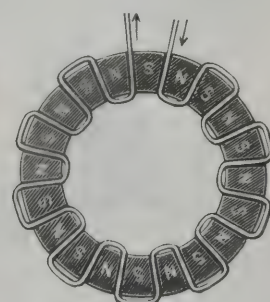

FIG. 10.—Joule's ZIG-ZAG ELECTRO-MAGNET.

of electro-magnet consisted of a rectangular iron block, having straight parallel grooves cut across its face, as in Fig. 9. This was described in Vol. VI. of Sturgeon's "Annals," p. 166. Its face was 6 $\frac{3}{4}$ ths inches square, and its thickness 2 $\frac{1}{10}$ ths inch. It weighed, with the conducting wire, 35 lbs.; and the armature, of the same size and 1 $\frac{1}{2}$  inch thick, weighed 23 lbs. The load sustained by this magnet was no less than 2,950 lbs. Roberts

\* "Scientific Papers," p. 40, and "Annals of Electricity," vol. v., p. 170.

inferred that a magnet, if made of equal thickness, but five feet square, would sustain 100 tons' weight. Some of Roberts's apparatus is still preserved in the Museum of Peel Park, Manchester.

On p. 431 of the same volume of the "Annals," Joule described yet another form of electro-magnet, the form of which resembled in general fig. 10; but which, in actual fact, was built up of 24 separate flat pieces of iron bolted to a circular brass ring. The armature was a similar structure, but not wound with iron. The iron of the magnet weighed 7 lbs., and that of the armature 4.55 lbs. The weight was 2,710 lbs., when excited by 16 of Sturgeon's cast iron cells.

In a subsequent paper on the calorific effects of magneto-electricity,\* published in 1843, Joule described another form of electro-magnet of horseshoe shape, made from a piece of boiler-plate. This was not intended to give great lifting power, and was used as the field magnet of a motor. In 1852, another powerful electro-magnet of horseshoe form, somewhat similar to the preceding, was constructed by Joule for experiment. He came to the conclusion † that, owing to magnetic saturation setting in, it was improbable that any force of electric current could give a magnetic attraction greater than 200 lbs. per square inch. "That is, the greatest weight which could be lifted by an electro-magnet formed of a bar of iron one inch square, bent into a semi-circular shape, would not exceed 400 lbs."

With the researches of Joule may be said to end the first stage of development. The notion of the magnetic circuit which had thus guided Joule's work did not commend itself at that time to the professors of physical theories; and the practical men, the telegraph engineers, were for the most part content to work by purely empirical methods. Between the practical man and the theoretical man there was, at least on this topic, a great gulf fixed. The theoretical man, arguing as though magnetism consisted in a surface distribution of polarity, and as though the laws of electro-magnets were like those of steel magnets, laid down rules not applicable to the cases which occur in practice, and which hindered rather than helped progress. The practical man, finding no help from theory, threw it on one side as misleading and useless. It is true that a few workers made careful observations and formulated into rules the results of their investigations. Amongst these, the principal were Ritchie, Robinson, Müller, Dub, Von Kolke, and Du Moncel; but their work was little known beyond the pages of the scientific journals wherein their results were described. Some of these results will be examined in my later lectures, but they cannot be discussed in this historical *résumé*, which is accordingly closed.

#### GENERALITIES CONCERNING ELECTRO-MAGNETS.

**Materials.**—In any complete treatise on the electro-magnet, it would be needful to enumerate, and to discuss in detail, the several constructive features of the apparatus. Three classes of material enter into its construction—first, the iron which constitutes the material of the magnetic circuit, including the armature as well as the cores on which the coils are wound, and the yoke that connects them; secondly, the copper which is employed as the material which conducts the electric currents, and which is usually in the form of wire; thirdly, the insulating material employed to prevent the copper coils from coming into contact with one another, or with the iron core. There is a further subject for discussion in the bobbins, formers, or frames upon which the coils are in so many cases wound, and which may in some cases be made in metal, but often are not. The engineering of the electro-magnet might well furnish matter for a special chapter.

#### TYPICAL FORMS.

It is difficult to devise a satisfactory or exhaustive classification of the varied forms which the electro-magnet has assumed; but it is at least possible to enumerate some of the typical forms.

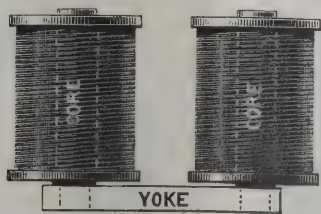

FIG. 11.—TYPICAL TWO-POLE ELECTRO-MAGNET.

1. **Bar Electro-magnet.**—This consists of a single straight core (whether solid, tubular, or laminated), surrounded by a coil. Fig. 3 (ELECTRICAL REVIEW, September 19th, p. 329) depicted Sturgeon's earliest example.

2. **Horseshoe Electro-magnet.**—There are two sub-types included in this name. The original electro-magnet of Sturgeon (fig. 1, p. 329) really resembled a horseshoe in form, being constructed of a single piece of round wrought iron, about half an inch in

diameter, and nearly a foot long, bent into an arch. In recent years the other sub-type has prevailed, consisting, as shown in Fig. 11, of two separate iron cores, usually cut from circular rod, fixed into a third piece of wrought-iron, the yoke. Occasionally this form is modified by the use of one coil only, the second core being left uncovered. This form has received in France the name of *aimant boîteux*. Its merits will be considered later. Sometimes a single coil is wound upon the yoke, the two limbs being uncovered.

3. **Ironclad Electro-magnet.**—This form, which has many times been re-invented, differs from the simple bar magnet in having an iron shell or casing external to the coils, and attached to the core at one end. Such a magnet presents, as depicted in Fig. 12, a

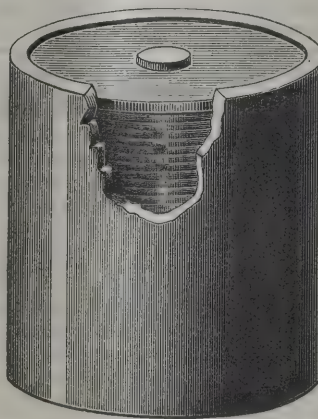

FIG. 12.—IRON-CLAD ELECTRO-MAGNET.

central pole at one end surrounded by an outer annular pole of the opposite polarity. The appropriate armature for electro-magnets of this type is a circular disc or lid of iron.

4. **Coil and Plunger.**—A detached iron core is attracted into a hollow coil, or solenoid, of copper wire, when a current of electricity flows round the latter. This is a special form, and will receive extended consideration.

5. **Special Forms.**—Beside the leading forms enumerated above, there are a number of special types, multipolar, spiral, and others designed for particular purposes. There is also a group of forms intermediate between the ordinary electro-magnet and the coil and plunger form.

#### POLARITY.

It is a familiar fact that the polarity of an electro-magnet depends upon the sense in which the current is flowing around it. Various rules for remembering the relation of the electric flow

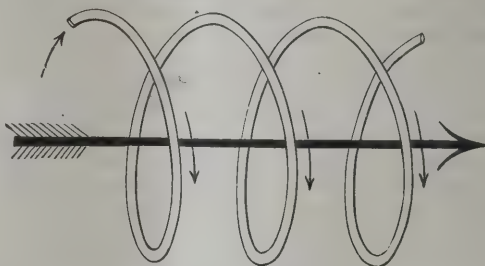

FIG. 13.—DIAGRAM ILLUSTRATING RELATION OF MAGNETISING CIRCUIT AND RESULTING MAGNETIC FORCE.

and the magnetic force have been given. One of them that is useful is that when one is looking at the north pole of an electro-magnet, the current will be flowing around that pole in the sense opposite to that in which the hands of a clock are seen to revolve. Another useful rule, suggested by Maxwell, is illustrated by fig. 13, namely, that the sense of the circulation of the current (whether right or left-handed), and the positive direction of the resulting magnetic force are related together in the same way as the rotation and the travel of a right-handed screw are associated together. Right-handed rotation of the screw is associated with forward travel. Right-handed circulation of a current is associated with a magnetic force tending to produce north polarity at the forward end of the core.

#### USES IN GENERAL.

Regarded as a piece of mechanism, an electro-magnet may be regarded as an apparatus for producing a mechanical action at a place distant from the operator who controls it; the means of communication from the operator to the distant point where the electro-magnet is being the electric wire. The uses of electro-magnets may, however, be divided into two main divisions. For certain purposes an electro-magnet is required merely for obtain-

\* "Scientific Papers," vol. i., p. 123; and "Phil. Mag.," Ser. 3, vol. xxiii., p. 263, 1843.

† "Scientific Papers," vol. i., p. 362; and "Phil. Mag.," Ser. 4, vol. iii., p. 32.

ing temporary adhesion or lifting power. It attaches itself to an armature, and cannot be detached so long as the exciting current is maintained, except by the application of a superior opposing pull. The force which an electro-magnet thus exerts upon an armature of iron, with which it is in direct contact, is always considerably greater than the force with which it can act on an armature at some distance away, and the two cases must be carefully distinguished. *Traction* of an armature in contact, and *attraction* of an armature at a distance, are two different functions. So different, indeed, that it is no exaggeration to say that an electro-magnet designed for the one purpose is unfitted for the other. The question of designing electro-magnets for either of these purposes will occupy a large part of these lectures. The action which an electromagnet exercises on an armature in its neighbourhood may be of several kinds. If the armature is of soft iron, placed nearly parallel to the polar surfaces, the action is one simply of attraction, producing a motion of pure translation, irrespective of the polarity of the magnet. If the armature lies oblique to the line of the poles there will be a tendency to turn it round, as well as to attract it; but, again, if the armature is of soft iron the action will be independent of the polarity of the magnet, that is to say, independent of the direction of the exciting current. If, however, the armature be itself a magnet of steel permanently magnetised, then the direction in which it tends to run, and the amount, or even the sign of the force with which it is attracted, will depend on the polarity of the electro-magnet, that is to say, will depend on the direction in which the exciting current circulates. Hence there arises a difference between the operation of a *non-polarised* and that of a *polarised* apparatus, the latter term being applied to those forms in which there is employed a portion—say an armature—to which an initial fixed magnetisation has been imparted. Non-polarised apparatus is in all cases independent of the direction of the current. Another class of uses served by electro-magnets is the production of rapid vibrations. These are employed in the mechanism of electric trembling bells, in the automatic breaks of induction coils, in electrically-driven tuning-forks such as are employed for chronographic purposes, and in the instruments used in harmonic telegraphy. Special constructions of electro-magnet are appropriate to special purposes such as these. The adaptation of electro-magnets for the special end of responding to rapidly alternating currents is a closely kindred matter. Lastly, there are certain applications of the electro-magnet, notably in the construction of some forms of arc lamp, for which it is specially sought to obtain an equal, or approximately equal, pull over a definite range of motion. This use necessitates special designs.

#### THE PROPERTIES OF IRON.

A knowledge of the magnetic properties of iron of different kinds is absolutely fundamental to the theory and design of electro-magnets. No excuse is, therefore, necessary for treating this matter with some fullness. In all modern treatises of magnetism, the usual terms are defined and explained. Magnetism which was formerly treated of as though it were something distributed over the end-surfaces of magnets, is now known to be a phenomenon of internal structure; and the appropriate mode of considering it is to treat the magnetic materials, iron and the like, as being capable of acting as good conductors of the magnetic lines—in other words, as possessing magnetic *permeability*. The precise notion now attached to this word is that of a numerical coefficient. Suppose a magnetic force—due, let us say, to the circulation of an electric current in a surrounding coil—were to act on a space occupied by air, there would result a certain number of magnetic lines in that space. In fact, the intensity of the magnetic force, symbolised by the letter  $H$ , is often expressed by saying that it would produce  $H$  magnetic lines per square centimetre in air. Now, owing to the superior magnetic power of iron, if the space subjected to this magnetic force were filled with iron instead of air, there would be produced a larger number of magnetic lines per square centimetre. This larger number in the iron expresses the degree of magnetisation in the iron; it is symbolised\* by the letter  $B$ . The ratio of  $B$  to  $H$  expresses the permeability of the material. The usual symbol for permeability is the Greek letter  $\mu$ . So we may say that  $B$  is equal to  $\mu$  times  $H$ . For example, a certain specimen of iron, when subjected to a magnetic force capable of creating, in air, 50 magnetic lines to the square centimetre, was found to be permeated by no fewer than 16,062 mag-

netic lines per square centimetre. Dividing the latter figure by the former gives us the value of the permeability at this stage of the magnetisation 321, or the permeability of the iron is 321 times that of air. The permeability of such non-magnetic materials as silk, cotton, and other insulators, also of brass, copper, and all the non-magnetic metals, is taken as 1, being practically the same as that of the air.

This mode of expressing the fact is, however, complicated by the fact of the tendency in all kinds of iron to magnetic saturation. In all kinds of iron the magnetisability of the material becomes diminished as the actual magnetisation is pushed further. In other words, when a piece of iron has been magnetised up to a certain degree it becomes, from that degree onward, less permeable to further magnetisation, and, though actual saturation is never reached, there is a practical limit beyond which the magnetisation cannot well be pushed. Joule was one of the first to establish this tendency toward magnetic saturation. Modern researches have shown numerically how the permeability diminishes as the magnetisation is pushed to higher stages. The practical limit of the magnetisation,  $B$ , in good wrought iron is about 20,000 magnetic lines to the square centimetre, or about 125,000 lines to the square inch; and, in cast iron, the practical saturation limit is nearly 12,000 lines per square centimetre, or about 70,000 lines per square inch. In designing electro-magnets, before calculations can be made as to the size of a piece of iron required for the core of a magnet for any particular purpose, it is necessary to know the magnetic properties of that piece of iron; for it is obvious that if the iron be of inferior magnetic permeability, a larger piece of it will be required in order to produce the same magnetic effect as might be produced with a smaller piece of higher permeability. Or, again, the piece having inferior permeability will require to have more copper wire wound on it; for in order to bring up its magnetisation to the required point, it must be subjected to higher magnetising forces than would be necessary if a piece of higher permeability had been selected.

A convenient mode of studying the magnetic facts respecting any particular brand of iron is to plot on a diagram the curve of magnetisation—i.e., the curve in which the values, plotted horizontally, represent the magnetic force,  $H$ , and the values plotted vertically those that correspond to the respective magnetisation,  $B$ . In fig. 14, which is modified from the researches of Prof. Ewing, are given five curves relating to soft iron, hardened iron, annealed steel, hard-drawn steel, and glass-hard steel. It will be noticed that all these curves have the same general form. For small values of  $H$  the values of  $B$  are small, and as  $H$  is increased  $B$  increases also. Further, the curve rises very suddenly, at least with all the softer sorts of iron, and then bends over and becomes nearly horizontal. When the magnetisation is in the stage below the bend of the curve, the iron is said to be far from the state of saturation. But when the magnetisation has been pushed beyond

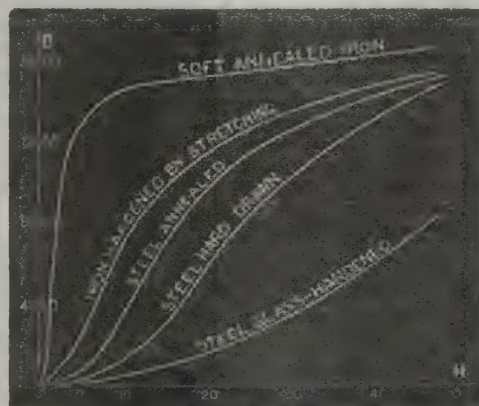

FIG. 14.—CURVES OF MAGNETISATION OF DIFFERENT  
MAGNETIC MATERIALS.

the bend of the curve, the iron is said to be in the stage approaching saturation; because at this stage of magnetisation it requires a large increase in the magnetising force to produce even a very small increase in the magnetisation. It will be noted that for soft wrought iron the stage of approaching saturation sets in when  $B$  has attained the value of about 16,000 lines per square centimetre, or when  $H$  has been raised to the value of about 50. As we shall see, it is not economical to push  $B$  beyond this limit; or, in other words, it does not pay to use stronger magnetic forces than those of about  $H = 50$ .

#### METHODS OF MEASURING PERMEABILITY.

There are four sorts of experimental methods of measuring permeability.

1. *Magnetometric Methods*.—These are due to Müller, and consist in surrounding a bar of the iron in question by a magnetising coil, and observing the deflection its magnetisation produces in a magnetometer.

2. *Balance Methods*.—These methods are a variety of the preceding, a compensating magnet being employed to balance the effect produced by the magnetised iron on the magnetometric needle. Von Feilitzsch used this method, and it has received a

\* The following are the various ways of expressing the three quantities under consideration:—

- $B$ —The internal magnetisation.  
The magnetic induction.  
The induction.  
The intensity of the induction.  
The permeation.  
The number of lines per square centimetre in the material.
- $H$ —The magnetising force at a point.  
The magnetic force at a point.  
The intensity of the magnetic force.  
The number of lines per square centimetre that there would be in air.
- $\mu$ —The magnetic permeability.  
The permeability.  
The specific conductivity for magnetic lines.  
The magnetic multiplying power of the material.

more definite application in the magnetic balance of Prof. Hughes. The actual balance is exhibited to-night upon the table, and I have beside me a large number of observations made by students of the Technical College by its means, upon sundry samples of iron and steel. None of these methods are, however, to be compared with those that follow.

3. *Inductive Methods.*—There are several varieties of these, but all depend on the generation of a transient induction current in an exploring coil which surrounds the specimen of iron, the integral current being proportional to the number of magnetic lines introduced into, or withdrawn from, the circuit of the exploring coil. Three varieties may be mentioned.

(A) *Ring Method.*—In this method, due to Kirchhoff, the iron under examination is made up into a ring, which is wound with a primary, or exciting coil, and with a secondary, or exploring coil. Determinations on this plan have been made by Stowletow, Rowland, Bosanquet, and Ewing; also by Hopkinson. Rowland's arrangement of the experiment is shown in fig. 15, in which B is the exciting battery; S, the switch for turning on or reversing the current; R, an adjustable resistance; A, an ampère-metre; and BG the ballistic galvanometer, the first swing of which measures the integral induced current. RC is an earth conductor or reversing coil wherewith to calibrate the readings of the galvanometer, and above is an arrangement of a coil and a magnet to assist in bringing the swinging needle to

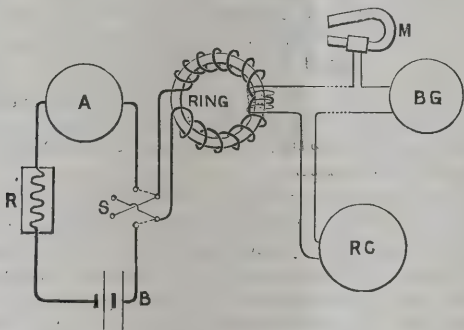

FIG. 15.—RING METHOD OF MEASURING PERMEABILITY (ROWLAND'S ARRANGEMENT).

rest between the observations. The exciting coil and the exploring coil are both wound upon the ring; the former is distinguished by being drawn with a thicker line. The usual mode of procedure is to begin with a feeble exciting current, which is suddenly reversed, and then reversed back. The current is then increased, reversed, and re-reversed; and so on, until the strongest available points are reached. The values of the magnetising force, *H*, are calculated from the observed value of the current by the following rule. If the strength of the current, as measured by the ampère-meter be *i*, the number of spires of the exciting coil, *s*, and the length, in centimetres, of the coil (i.e., the mean circumference of the ring) be *l*, then *H* is given by the formula—

$$H = \frac{4 \pi}{10} \times \frac{s i}{l} = 1.2566 \times \frac{s i}{l}.$$

Bosanquet, applying this method to a number of iron rings, obtained some important results. In fig. 16 are plotted out the values of *H* and *B* for seven rings. One of these, marked J, was of cast steel, and was examined both when soft and afterwards when hardened. Another, marked I, was of the best Lowmoor iron. Five were of Crown iron, of different sizes. They were marked for distinction with the letters G, E, F, H, K. In the accompanying Table are set down the values of *B* at different stages of the magnetisation.

TABLE OF VALUES OF *B* IN FIVE CROWN IRON RINGS.

Name.	G.	E.	F.	H.	K.
Mean diam. bar thickness.	91.5 cm. 2.535	10.085 cm. 1.298	22.1 cm. 1.292	10.735 cm. 0.7187	22.725 cm. 0.7544
Magnetising force.					
0.2	126	73	62	82	85
0.5	377	270	224	208	214
1	1,449	1,293	840	675	885
2	4,564	3,952	3,533	2,777	2,417
5	9,900	9,147	8,293	8,479	8,884
10	13,023	13,367	12,540	11,376	11,388
20	14,911	14,653	14,710	14,066	13,273
50	16,217	15,704	16,062	15,174	13,890
100	17,148	16,677	17,900	16,134	14,837

I have the means here of illustrating the induction method of measuring permeability. Here is an iron ring, having a cross-section of almost exactly one square centimetre. It is wound with an exciting coil supplied with current by two accumulator cells; over it is also wound an exploring coil of 100 turns connected in

circuit (as in Rowland's arrangement) with a ballistic galvanometer which reflects a spot of light on the screen. In the circuit of the galvanometer is also included a reversing earth-coil. As a matter of fact, this earth-coil is of such a size, and wound with so many convolutions of wire that, when it is turned over, the amount of cutting of magnetic lines is equal to 840,000, or is the same as if 840,000 magnetic lines had been cut once. By adjusting the resistance of the galvanometer circuit, it is arranged that the first swing due to the induced current, when I suddenly turn over the earth coil, is 8.4 scale divisions. Then, seeing that our exploring coil has 100 turns, it follows that, when in our subsequent experiment with the ring, we get an induced current from it, each division of the scale over which the spot swings will mean 1,000 lines in the iron. I turn on my exciting current. See: it swings about 11 divisions. On breaking the circuit, it swings nearly 11 divisions the other way. That means that the magnetising force carries the magnetisation of the iron up to 11,000 lines; or, as the cross-section is about 1 square centimetre, *B* = 11,000. Now, how much is *H*? The exciting coil has 180 windings, and the exciting current through the ampèremeter is just 1 ampère. The total excitation is just 180 "ampère-turns." We must, according to our rule given above, multiply this by 1.2566 and divide by the mean circumferential length of the coil, which is about 32 centimetres. This makes *H* = 7. So if *B* = 11,000 and *H* = 7, the permeability (which is the ratio of them) is about 1,570. It is a rough and hasty experiment, but it illustrates the method.

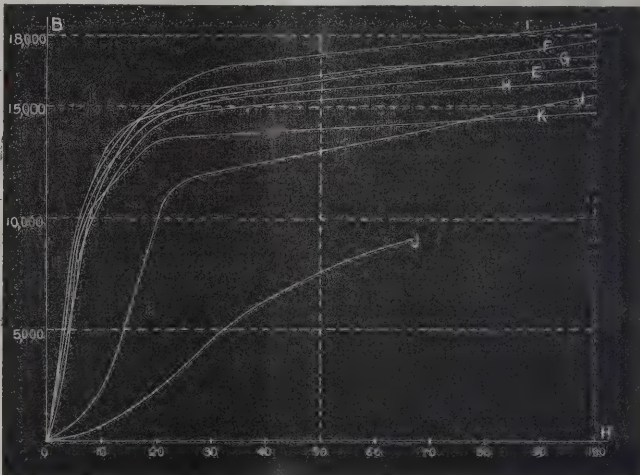

FIG. 16.—BOSANQUET'S DATA OF MAGNETIC PROPERTIES OF IRON AND STEEL RINGS.

Bosanquet's experiments settle the debated question whether the outer layers of an iron core shield the inner layers from the influence of magnetising forces. Were this the case, the rings made from thin bar iron should exhibit higher values of *B* than do the thicker rings. This is not so; for the thickest ring, G, shows throughout the highest magnetisations.

(B.) *Bar Method.*—This method consists in employing a long bar of iron instead of a ring. It is covered from end to end with the exciting coil, but the exploring coil consists of but a few turns of wire situated just over the middle part of the bar. Rowland, Bosanquet, and Ewing have all employed this variety of method; and Ewing specially used bars the length of which was more than 100 times their diameter, in order to get rid of errors arising from end-effects.

(To be continued.)

### ABSTRACTS OF PUBLISHED SPECIFICATIONS, 1889.

11426. "Improvements in the mode of driving, by means of electric motors, tramcars and other vehicles, and in apparatus for reducing in transmission to the axles of such vehicles the speed of rotation derived from electric and other motors." P. A. NEWTON. (Communicated from abroad by W. Main, of New York.) Dated July 16. 1s. 6d. Consists, in part, of an improvement upon what is commonly known as Watt's sun and planet gear. 8 claims.

11589. "Improvements in electric conductors, and in laying and supporting conductors within conduits." R. E. B. CROMPTON. Dated July 20. 8d. Relates to further improvements connected with Letters Patent No. 7655 of the 25th May, 1888. 5 claims.

11847. "Improvements in the distribution of electrical energy." SIEMENS BROTHERS & Co. (Communicated from abroad by the firm of Siemens and Halske, of Berlin.) Dated July 25. 8d. Claims:—1. The method of distributing electrical energy wherein three or more secondary conductors that supply the groups of consuming apparatus are combined with one or more current

generating machines and one or more transformers in such manner that the current generating machine or machines is or are connected by two main leads to the primary coil of the transformer the secondary coil of which is divided into sections which are connected to the said three or more secondary conductors substantially as described. 2. The modification of the method of distribution referred to in the preceding claim wherein the transformers consist of motor-generators having two or more generator armatures and driven by the current from the main current generator, the generator armatures of the motor transformers being coupled in series and connected to the said three or more secondary conductors substantially as described.

12772. "Improvements in means or apparatus for the generation and conversion of electric energy." A. DE CASTRO. Dated August 13. 8d. Consists in the employment of finely subdivided or comminuted magnetisable metal, usually iron filings, arranged in such way as to be loose or free to move, so that the particles may vibrate, and subjected to the action of magnetic lines of force derived either from permanent or electro-magnets, or from an exciting coil or coils. 4 claims.

12982. "Improvements in actuating mechanism for electrical switches." T. BARTON. Dated August 17. 6d. Claim:—The combination of a pulley or roller working against a lever actuated by a spring or working against a spring only, of special design, without the lever, and applied for the purpose of forcing the contact maker home in both directions, and applied to a switch for making and breaking electric circuits.

13371. "Improvements in electric telegraphic apparatus, applicable also to other electric signalling or indicating apparatus." T. H. PARKER and G. W. FAIRALL. Dated August 24. 8d. Has for its object to automatically relay from a battery the particular current which may be in circuit, whether it be of the positive or negative kind, and further to deflect the needle or actuate any other electrical instruments in a much more sensitive or economical manner than has been previously done. The relay instrument consists of five or more permanent magnets, upon each of which is mounted an electro-magnet, by which induced magnetism is obtained; two of these require to be positive, two negative, and the other either positive or negative, as may be preferred. 3 claims.

13859. "Regulator for electric lighting." E. J. HOUGHTON. Dated September 3. 6d. Claim:—1. The gradual insertion in or withdrawal from a circuit of resistance by means of a solenoid and vessel containing mercury or other conducting fluid.

14162. "Improvements in treating and rectifying or ageing alcohol or alcoholic liquors or the like by electricity." A. DE MERITENS. Dated September 7. 4d. Claim:—In the treatment and rectification or ageing of alcohol or alcoholic liquors and the like by electrical action the employment of a salt such as bi-sulphite of soda for the purpose described.

18018. "Improvements in electro-magnetic brakes for railway and similar vehicles and in means for increasing the adhesion between the wheels and rails." A. J. BOULT. (A communication from E. E. Ries and A. H. Henderson, of America.) Dated November 12. 8d. This invention has reference to a system of electro-magnetic brakes for wheeled vehicles, more especially for railway cars, and the same is combined with and is designed to operate in conjunction with a system of electro-magnetic traction increasing devices, for which letters patent have been obtained of Great Britain, No. 4,280, dated 20th March, 1888. 18 claims.

## THE VALUE OF DETAIL IN THE CARE AND LABOUR OF ELECTRIC LIGHT STATIONS.\*

By A. J. DE CAMP.

IT certainly is a fact apparent to any one who has had the handling of electric light stations, that it is essentially a business of detail. The larger items about the business are very easily handled. They will take care of themselves if they are put in the right direction; but there is an infinite number of small things which very materially affect the successful operation of an electric light station. As an illustration of what I mean by that term, I will say that after considerable reflection and dividing the items worthy of care and attention in the management of the business under fifty heads, all of which have to be kept track of, and all of which are a positive and a direct item of expense or income, I find five items which I have had to class as miscellaneous expenses. These include all those items of expense which have a bearing on the business in general, not chargeable to any one of the particular heads under which I have seen fit to group the business.

I find that the amount involved in miscellaneous items for the last year, in one company, was about \$15,000; the space occupied on the books of the company to cover these small items was twice as much as the whole of the other part of the business. The items there reached from one penny up. There is no doubt but that detail may be carried to such an extent that it becomes burdensome. It may become unprofitable on some particular item, but we can only treat this matter as a whole. In one item of carbons alone the reduction in the expense of the carbon caused after a system was adopted by which they were accounted for on the basis of the inches, there was a saving of nearly 50 per cent. in that item alone.

Another important thing is the matter of discipline, because it is utterly impossible to get the detail part of your business thoroughly carried out unless you have a thorough discipline about your station. The most important item in the whole operation of an electric light station in point of dollars and cents is that of labour, and I do not see but what it will always be the case. I remember there was a time when we thought that sixty lamps on an ordinary circuit was a day's work for a man. Now they trim a hundred lamps more easily than they used to trim sixty, and my own judgment is that in the course of time we will work up so that 150 will be no harder than 100.

A custom of dealing with labour, I think, which requires the accounting of every minute of time for which a man is employed, has a very beneficial effect. I think that alone can be credited with a reduction in the pay-roll of some 25 per cent. A custom has been adopted by me of having a slip furnished to the workman by which he accounts for every hour of service; this gives the man who has charge of him an opportunity of judging for himself whether that man has employed his time properly during the ten hours. In the early history of the business it was the custom of my company to do a great deal of work without charge. That was done for policy sake. The number of men apparently required for the operation of the station was very far in excess of what anybody ever represented it to be or supposed it to be. In looking into it, we found that there were two or three men working here, and two or three there, and three or four somewhere else. What were they doing? Well, they were making changes, shifting the position of lamps—they were doing this, that, and the other thing. Well, we were going to be through with that and let these men go, we thought. But the fact is they never did go—they hung right straight on all the time. We closed that month and started in the next on the basis of charging for all work. The basis of the charge was mainly for the labour, charged at 30 cents an hour, and all waste materials. We did not charge for anything that would be incorporated into our own property.

At that time, I think, we were running about 350 lights, and when at the end of the month we charged that up and it amounted to over \$800. We tried to collect it, but I presume we did not collect more than \$200 out of the \$800. People demurred and would not pay it. But it brought the thing to an understanding. Now, no work is done after the first installation unless it is to be paid for by our customer, and we get an order from our customers in which they order the work to be done and to charge it to their account. That brought the next month's charges down, and all we had occasion to charge them was something less than \$200. There could be no better proof in the world than that very fact that, as long as people did not have to pay for a thing, they were very free to indulge their fancies.

Another point: We send a man out to do a job and he comes in and charges three, four, five, six, or ten hours' time. The man for whom that work is done cannot account for more than an hour or two. Then comes your discussion on the payment of that account, and it is as a great trouble. We know nothing; we charge a man's time from the time he leave the station till the time he gets back and reports to us, and whether he has put in that amount of time, less the

\* Delivered before the N. E. L. A., Cape May, August 20th, 1890.

time of coming and going, of course we have no means of knowing; at least, we did not, but we get nearer to it now. That is one of the things that takes a great deal of time, and I have noticed that our charges for that sort of work are very much more equitable, according to the judgment of our customers, than they have been heretofore; and, moreover, we find that the men do a great deal more work.

Another question which I think can be very profitably discussed is that which relates to small matters of income on your revenue account. The electric lighting business is not in such condition that you can take the ordinary stand and say to the public, "You will take just what we can give you, and just as we want to give it to you, or get nothing." We make our contracts as specific as we can; but we have not got a contract under which we have not given more service than we agreed to give in that contract. The service rendered is never below the standard. We have lights running on the 12 o'clock service plan; and our contracts for that service cover seven hours of maximum burning. That would mean strictly that at no time was the service rendered by those lights to exceed seven hours, which, in the winter months, is from five to 12. But that does not do, because five o'clock is not early enough in three or four months of the year, when the lamps are sometimes lighted as early as three o'clock. It means rather an average of seven hours than it does a maximum of seven hours. In any city where there is a restriction on the running of wires, it is necessary that you put half night lights on all night circuits, with the object and purpose of switching them off, individually perhaps at 12 o'clock. A customer can hardly be relied upon to do that, and the only safe way to do it is to have them switched off by your own *employés*. It is the same with all night lights, which might be run, and sometimes are run. Those conditions must be met. You must give the people what they want, or you will finally lose your business, and you will have to be getting new business all the time.

As long as I have been connected with this association, and as large an acquaintance as I have among electric light central station men, I never have found any one yet who seemed to have any appreciation or any interest in knowing just exactly what his product cost him on the same basis on which he sold it. To get at the cost of a light, or of any particular part of it, it is very generally figured up as a horse-power. But the point that I have always contended for is this. I rent a light for a given length of time, for a year, if you choose, which is the most favourable contact that I consider that we can make, because it gives us the longest service. In doing that you figure it on the basis to furnish light 312 nights per year, which you sell at so much per light. Now, you really want to know, not what the 312 lights cost you, and how much you get for them, and take the difference, and let that be profit or loss just as it happens to be, but you want to know just what each one of these lights cost you, and you want to know it as a whole; you do not want to know whether it takes one horse-power or two horse-power, or half a horse-power, as there are a great many other things besides horse-power that enter into this question.

Another thing that I find to be a very common practice is, to have a uniform price for a light of a certain character, whether the contract is for furnishing light for six months or for a year. The same rate for the longer and the shorter term is unjust to your long contract customers. It is a very easy thing to rent lights during six months of the year, commencing the first of September, October or November, and it is a very easy thing to keep such customers, because they want the lights most at that time. But in the summer time people discontinue the use along about the first of March, April, May or June, and so you have an idle lamp during the summer, in which you have your money invested. I contend that the user of that lamp has no right to expect to get that light at the same price per diem as the man who pays you for a service of 312 nights in the year. But that is almost universally done.

There is just as much reason for a graduated scale of prices based upon the amount of service you get from your customer as there is for fixing the price for a 10 o'clock circuit, a 12 o'clock circuit, or an all-night circuit.

When that first became apparent to me the first effort I made to equalise the prices on that basis showed me that there was really nothing to go upon excepting guess work. After the first year's experience I had the result of my own experience to go by, by means of which I could work it out in a little better shape. But I found myself doing an injustice to our customers when I thought that I was doing an injustice to myself. I found that I was charging more people too much on that basis and others too little. This puts the company in the position of making a uniform contract in which they can say to every customer, or to every person that comes into the office, that the company will duplicate for him any contract that it has on its books.

### INDIAN TELEGRAPHS.

THE following information respecting the telegraphs of British India is extracted from the "Moral and Material Progress and Condition of India." The length of telegraph line and cable in India is now 33,462 miles, of which 1,568 miles represent the extensions of 1888-89. The number of messages for that period were 2,978,888, an increase of 176,669 over the previous year. The increase of messages was wholly under the head of "private messages," there having been a considerable decrease in the number of State or public service messages. The receipts were Rx. 632,247, yielding a surplus of Rx. 198,024 on the revenue account, and equal to 4.45 as against 5.46 per cent. in the preceding year on the capital outlay. The decrease of receipts was due to the reduction in the number of State messages, especially in Burmah.

The additions to the capital expenditure during the year amounted to Rx. 174,362 or Rx. 60,593 less than the previous year. On the Indo-European Telegraph line *via* Teheran the nett revenue was £19,138, equal to 1 $\frac{3}{4}$  per cent. on the capital outlay of £1,124,126, but if the line be debited with the annuity of Rx. 18,827, payable to the shareholders of the late Red Sea Telegraph Company, the surplus of the year is reduced to Rx. 1,111.

### CORRESPONDENCE.

#### Electrical Heterodoxy.

Having read your article in last week's issue on "Electrical Heterodoxy," it recalled to memory a little piece of apparatus I devised some years ago, for the amusement and instruction of some juvenile friends. I think it gives experimental proof of your explanation of the test tube experiment.

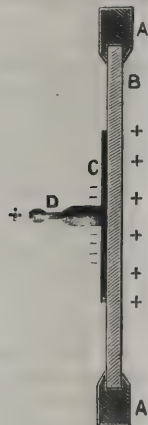

An ordinary school slate is taken, and the slate removed and a sheet of glass inserted in the frame. In the centre of one side of this glass is attached a sheet of tinfoil, and to centre of foil is attached a smooth, round-ended cork neatly covered with tinfoil; from end of cork projected a small metal ball. The sketch represents a section.

On warming the apparatus and rubbing the plain surface of glass with a piece of silk for a short time, a spark may be drawn from the projecting ball on opposite side of glass.

Must I conclude the electricity passed from the rubbed side and through the system and out by the ball? Without going into the controversy of whether electricity is generated or separated, the explanation the juveniles received was, that, by the expenditure of an amount of muscular energy, the plain surface is positively electrified, which induces a negative char e

on the other surface, thus disturbing the electric equilibrium of the whole system with the result of the exhibition of positive electrification on the ball.

The fact that electricity did not pass through the glass was shown in a very simple way, holding the slate horizontally, cork down, and placing a sheet of foil on the glass, then connecting it with the ball by means of a discharger, when a second spark occurs, and the equilibrium is restored.

A, A, Slate frame; B, Sheet of glass; C, Tinfoil; D, Cork and projecting ball;  
+ —, Shows condition of electrification, though — sign should be between foil and glass.

Now, I think, this exactly shows what occurs in the test tube experiment, the inner surface of which is represented by the uncoated surface of the glass. To my mind, this test tube experiment of the apparent passage of a spark through the glass, rather points to the probability that conduction is an effect of polarisation.

Assuming the spark an evidence of conduction, and its passage an evidence of current, then if the conduction is absolute, the glass should be perforated; but, no, there is a break of continuity, and this assumed current takes another quality, and one that we can grasp, it apparently gets through that glass; but how, and does it get through? No, it takes up the quality assigned to induction, the dielectric glass is polarised, we know the inner and outer surface of the end of that test tube must be under a state of polarisation, one surface being positively electrified and the other negatively; this is a fact, because we know the effect produced by a charge in this way.

Are we driven to the conclusion that that which we call current has passed by conduction through the glass by the agency of polarisation or induction; if this be so, then what is the difference between conduction and induction, and are they not *both* explainable by polarisation? The glass end of the test tube is equally a portion of the path; then why should we conclude the energy passed through the air space by conduction and through the glass by induction; rather should we say the whole passage is completed from atom to atom through the agency of polarisation, and therefore induction, or equally conduction; but why this clashing of words, why not say at once, polarisation?

I do not see that the insulated gas flame experiment proves more than that the flame is electrified in sign similar to that from which it is deflected. I have not seen the original description of the experiment, but base my conclusion on the description in your issue of last week. It does not follow that because we speak of + and — electrification and polarisation that we believe, or even assume, there are two forces.

There is such a thing as stress and strain, and I, for one, can see no reason why we should consider electric stress and polarisation as distinct. I am firmly of belief the generation of current by the passage of a conductor across a magnetic field is one of strain, and bearing in mind that if a bar of copper be suspended in a magnetic field, it will, diamagnetically, set in a definite direction. What occurs if that bar is urged through the field in a *definite position*? Must there not

be a strain on the particles of that bar, and will they not turn toward the position in which the bar would set if free, and return from that position as the bar passes out of the field, do not the atoms, molecules, or particles of that bar oscillate, turn or rotate?

What do we find when the bar is in closed circuit and approaches and enters the field, and as the atoms, molecules, or particles are strained, a current of electric energy is urged in one direction, and as the bar passes out of the field and the atoms, molecules, or particles swing back, a current of electric energy is urged in opposite direction? Shall we not call this straining or swinging back dynamic or oscillating polarisation, and polarisation in which set occurs, static polarisation? Having got thus far, is it possible that Faraday, Tyndall, and others, in their brilliant diamagnetic experiments, omitted to test whether an electrostatic effect is produced by resisting the diamagnetic movement through fixing, say, the bar of copper, and thus allow the atoms, molecules, or particles to assume a polarised set?

It would be an instructive discovery to find by diamagnetic experiment that the set polarisation means static electrification, and the oscillating polarisation dynamic electricity. There is room for thought and experiment in this direction.

#### French v. English Steel.

Kindly insert the enclosed letter in your valuable REVIEW, and oblige, yours respectfully,

J. A. Parkes.

September 19th, 1890.

"19th Sept., 1890.

"W. H. Preece, Esq., F.R.S.

"Sir,—I have been much interested by reading in the ELECTRICAL REVIEW the report of your paper on the quality of magnetic steel, and much pleased to observe that the sample magnets made by Mr. Marchal are superior to the others. The cause of my satisfaction is that the steel used in making these samples was furnished by me to Mr. Marchal. I have supplied him for some years past, and the magnets which procured him the only award given specially for magnets in the Paris Universal Exhibition of last year were also made of MM. Levick, McGillivray & Co.'s steel sold by my intermediary to Mr. Marchal.

"Your conclusion, therefore, that French steel is better than English needs modifying. Nevertheless, I shall not envy the reputation of French steel, if the French Government and public companies continue to purchase of me as heretofore.

"I hold myself at your service to furnish any further information that can be of use to you in pursuing your interesting and practically useful investigations.

"I am, Sir,

"Yours very respectfully,

"J. A. PARKES,

"Paris Agent of Levick, McGillivray & Co."

#### Prof. Elihu Thomson's Alternator.

The publication of an abstract of my specification describing an alternating dynamo of new design has elicited some correspondence in your paper, concerning which I think I may make a few statements.

The principle of utilising the changes of magnetic force without reversal in generating currents is certainly not new, as I designed machines working on this principle as far back as 1877–78.

The merit of the new machine is that it is a practicable machine to build and to operate, and at the same

time that its efficiency will undoubtedly be high, as the preliminary tests of a machine built to run 1,000 lights have shown that it can carry 1,500 lights quite efficiently. The indications go to show that machines can be made to have a commercial efficiency of 90 per cent. or over.

I am tempted to be somewhat amused at the criticisms made on the character of the Field as being inefficient, and I refer particularly to the statement of Pyke and Harris in their letter appearing in your issue of August 29th:—"Whereas, in Prof. Thomson's machine, it is apparent there is a considerable loss in the Field, more particularly the revolving part of the same." Now, it happens that the machine, as constructed, shows no evidence of any heating in the revolving portion as well as other portions; but, on the other hand, that this portion of the machine keeps delightfully cool, and that the heating is in the wire and only that due to whatever density of current may at any time be flowing.

Concerning the theory of the machine, it may not be out of place to give my views on the subject. I do not think that the stationary iron which supports what may be termed the armature bobbins, is entirely free from reversals of magnetism, but that under heavy loads there may be slight reversals occurring in certain portions of the iron, due to the flow of the armature currents themselves, and particularly those portions influenced by the armature wire which are not at the same time under the influence of the field poles. Whether the lines of magnetism are actually carried around with the revolving consequent poles or not is a question which it is difficult to answer, but the actions would be the same whether they are or not. If they are carried around by the consequent pole, the coils opposite them or the armature wire would be cut by concentrated bundles of lines issuing from the revolving consequent pole to the exterior iron, and if the lines do not rotate with the pole, then the armature wire would be cut by lines springing back from one division of the consequent pole to the next succeeding division as such pole revolves.

The details of the design will probably determine which of these actions will take place, and, in most cases, perhaps both the actions of bundles of lines carried forward, combined with the recession of lines backwards from one division of the revolving pole to the next succeeding, may really take place.

In the large machine which I have, the laminated iron carrying the armature coils or induced coils is divided into a number of sections or segments of a ring, and machines have also been built in which there is no iron projecting from the outer laminated portion towards the revolving pole. In this case, of course, the closure of the magnetic circuit is almost uniform throughout the revolution.

I had not intended to publish anything concerning this machine until the work of building and testing the machines of large size had been completed, but the extracts from my specification have led to sufficient discussion to warrant me in making the statements preceding.

Elihu Thomson.

Lynn, Mass., September 10th, 1890.

#### Re The Bath Installation.

In reply to Mr. Massingham's letter I wish to point out that my quarrel was on September 3rd. The alleged carelessness was based on an accident occurring at midnight, September 1st.

You will find on referring to my report of the breakdown of August 31st, dated September 1st (and which was written early in the morning, posted to catch an early mail, and which would be delivered at your office during the afternoon or evening), that I did not conceal the fact that I was working on the installation.

With the failure of August 31st, due to carelessness in the boiler-house, I, as engine-driver, had nothing to

do, and you will find the information I supplied you with to be correct, should you care to make further enquiries.

You are at liberty to publish all the above or any extract of it with my full name and address.

Charles Powell.

September 22nd, 1890.

#### Fire Office Rules.

As you have mentioned my name in connection with the recent correspondence in the *Times*, of which the leading article on Fire Risk Rules in your issue of the 20th inst. is the result, perhaps you will permit me to make a few further remarks on the subject.

There is unfortunately a tendency in certain quarters to make light of the difficulties incidental to electric light wiring, and an idea that no great experience is required to enable anyone acquainted with the ordinary principles of electrical science to draw up trustworthy rules.

Contractors and others who have experienced the unforeseen, perplexing, and vexatious failures of insulation that from time to time occur even with the best of work and material, will agree that this is not the case at all, and that the practical difficulties are in some cases much greater than many apprehend.

As I have already stated in the *Times*, it is much to be desired that, if an electrical committee be appointed by the Institution of Electrical Engineers, or any one else, to confer with the insurance companies and draw up new rules, care shall be taken to arrange that the majority of those forming such a committee be men having a real practical experience of the subject from the contractors and supply companies points of view, and not mere secondhand information or theoretical knowledge, however eminent.

That a word of warning is required as to this, is evident from a glance at the names of those who composed the committee that drew up the existing Institution Fire Rules. The list comprises men of the highest distinction and standing in the electrical world; men whose services to science it would be impossible to overestimate; but among the whole 22 names, of which seven are those of professors, there are not above half-a-dozen who can possibly have had any practical experience of electrical wiring—at all events, as commercially carried out.

Prof. S. P. Thompson has recently designated the Institution Rules as "a dead letter," and as "invertebrate." On the contrary, they are in many respects an admirable set of regulations, but it is idle to deny that they are capable of considerable improvement, and that a committee having a larger admixture of the practically experienced element could now frame a set very superior in many particulars.

The electrical industry will, I am confident, agree as to this:—If any one set of rules is to be universally and exclusively adopted, let us have these rules as perfect and as definite as practical experience can make them. Let these rules clearly state what is and what is not admissible, and distinctly differentiate between those regulations that are obligatory and those that are merely recommended. Let us have a thoroughly competent committee to draw the rules up, and let this committee be a standing one, so that the rules may be revised from time to time as the progress of electrical science and the accumulation of experience renders this necessary.

By whom, whether the Institution of Electrical Engineers or the Electrical Trades Section of the London Chamber of Commerce, such a committee, is appointed, is of secondary importance, provided the insurance companies are satisfied and due weight and authority be assured. The real question of moment is the constitution of the committee itself and the practical competence of those who serve on it.

A. A. Campbell Swinton.

## "A REVOLUTION IN THE COPPER MANUFACTURING INDUSTRY."

A WELL-KNOWN promoter was once asked how it was that the public so readily subscribed to unsound schemes, formed upon lines that had been exposed years before, and he replied, "My dear sir! There's a fresh crop of fools born every day." If this dictum be true, it is possible that Elmore's Austro-Hungarian Patent Copper-Depositing Company may be subscribed four times over, as, according to the prospectus, has been the usual fate of other members of the family.

This company is formed for the purpose of acquiring the Elmore patents for the empire of Austria-Hungary at a price of £50,000 in cash, £50,000 in shares, and the premium on the shares now offered. 75,000 shares are now offered. The premium is 10s. per share, so that the possible purchase price is £137,500. And what does the company obtain in exchange for one hundred and thirty-seven thousand five hundred pounds? Two patents, of many figures, relating to the discovery made by Messrs. Elmore for manufacturing copper articles direct from rough copper bars.

Our readers are by this time familiar with the material of which a copper-depositing prospectus is made. The new applicant for public approbation has the usual Elmore features. There is a description of the process, a reference to reports on the process, a summary of the advantages of the process, and a so-called estimate of profits. There is also a paragraph headed, "Character of Investments." We have our own opinion of the character of the investment, which does not accord with the view of the prospectus; but there is one statement in this paragraph which we think should be further enquired into. It says the investment is offered in a company formed to work an invention *producing, at a cost hitherto unknown*, articles admittedly of unprecedented quality, and in large demand. The phrase which we have italicised is, of course, intended to mean that the

articles are produced at a less cost than has been known before by any other process; but, unless we are much mistaken, it may be applied to the process the patents for which it is proposed to sell. If we had doubts on this point, they would be set at rest by the rapid multiplication of Elmore Companies.

We see it reiterated in their prospectuses that the Elmore process is believed to be the most important metallurgical discovery of recent years, and that it will take the same leading position in the copper industry that Bessemer's did in iron and steel. It is not stated who formed this opinion or who subscribes to it as an article of faith, but the mere statement is of value, for it gives an opportunity of recording that Bessemer has received a million in royalties. We need not trouble to make a comparison between the two processes or the methods of their development. We do not see any comparison in their respective values. It took Bessemer some years, and there was a good deal of solid work done, before he got his million. Hardly any time has elapsed since Elmore took out his patent, and no commercial work at all has been done, yet the Elmore people must have absorbed a good many hundreds of thousands of pounds already, and the Timbuctoo Company is not out yet. We wish Sir Henry Bessemer's name were invoked for a better purpose, and placed in better company.

We have to consider what the Elmore process is, and on what grounds a company is asked to pay £137,500 for the Austro-Hungarian rights. The electro-deposition of copper is an old and well-known process. It is alleged that for commercial purposes there is not sufficient tenacity in the deposited coating, and that some mechanical assistance is required to obtain the necessary result. We do not know exactly how much Mr. Elmore claims to have discovered, or how much he claims to have invented, but speaking broadly we believe that the application of the burnisher constitutes his sole claim. Quite suffi-

cient to entitle him to credit as a discoverer if the application enables some useful purpose to be served which could not have been served before, and quite sufficient to entitle him to reward as an inventor if the invention is novel and the patent for it can be sustained. But we are without any information of a practical character that the invention is a useful one. Moreover, as the "Transactions of British Naval Architects," for 1889 show, there is something to be actually said in opposition to electrically deposited tubes. Mr. Clark (an exhibitor at Glasgow Exhibition) said:—"We have made tubes experimentally in the same way (electro-deposited), but they have not proved either so good or so cheap as tubes made by the system now in use, although the copper gives a remarkably close grain fracture, and is excessively tough. At the same time the point which I particularly draw your attention to is this, that at the temperature of  $390^{\circ}$ , which I understand is the working pressure of these main steam pipes, the electro-deposited copper gives no better result; in fact, a shade worse result than seamless-drawn copper . . . . Moreover, as the diminution in strength between the normal temperature and  $390^{\circ}$  in the case of the electro-deposited copper is so very great, it would seem logically to follow that if you got anything higher than  $390^{\circ}$  it would decrease in the same ratio, and would thus become much worse than a seamless solid-drawn copper pipe, &c.," and to conclude—"I may say in conclusion that we have given considerable attention and time to this question of making tubes by electro-deposition, but have come to the conclusion that it is not so satisfactory a method as that of making them by the seamless drawn process." Mr. W. Parker also reports:—"The tenacity of the electro-deposited copper was, in its cold state,  $24\frac{3}{4}$  tons per square inch, the solid drawn had a tenacity of 20 tons, and the plate copper a tenacity of about 14 tons. When subjected to high temperatures these high tenacities vanish very quickly. At a temperature of  $390^{\circ}$  F., equal to the pressure of steam at a pressure of 200 lbs. per square inch, the electro-deposited falls to 15.3, or a loss of 61 per cent.; the solid-drawn to 14, or 30 per cent.; and the plate to  $10\frac{1}{2}$ , or 25 per cent."

Mr. Stepney Rawson has informed a shareholders' meeting that some incredulous copper worker (name not stated) was astounded at the result attained. Directors have made more or less vague statements of the progress of the work and its wonderful value, and the great misfortune of the breakdown of an engine, but the commodity is hardly yet on the market. The value of the process commercially is an unknown quantity. Yet companies are brought out in a prodigal manner, and money squandered for rights of one sort and another in more prodigal fashion. If the engine had not broken down the manufacturing might have been in full swing, the cost of the process known, and estimates dispensed with. We hope the makers will receive adequate reward for the breakdown in event of its proving advantageous to the parties interested in the promotion of these further companies.

It is useless to attempt to disguise the fact that

Elmore's process has, up to the present, been simply a promoters' puppet. Parallels are to be found, and the eventual outcome may consequently be anticipated with certainty. The original Brush Company will be in the recollection of our readers. What became of its numerous offspring? They were simply acquired by and re-amalgamated with the parent company at a very considerable direct loss to investors and indirect loss to the electrical profession. Water-Gas is a later example. Perhaps there is a greater similarity to the famous Date Coffee Company in the Elmore system of issues. The Date Coffee Company made a great deal of a contract entered into with Messrs. Mac Something to take their output for a certain period. It was worthless. We notice a similar arrangement, only less definite, on the part of the Elmore Wire Company to dispose of their output for 1891. We wonder what the output of 1891 will amount to, or whether it is certain there will be any output at all?

Vagueness and uncertainty, with a good deal of unhealthy high-falutin, has been the characteristic of the Elmore information up to now. We turn in vain to the prospectus of the Austro-Hungarian Company for anything different. In the first paragraph the process is described as "extremely valuable." This is about the only definite statement the directors permit themselves to make on their own authority. The principle of devolution of responsibility is ably carried out in the remainder of the prospectus.

It is surprising that any set of business men should permit their names to stand at the head of a prospectus with such a paragraph as that headed, "Estimated Profits." In the English company's prospectus it was estimated that under certain most disadvantageous circumstances the profits would amount to over £100,000 a year. The directors of the English Wire Company were confident that another £100,000 a year would fall to that company's lot. That makes £200,000 a year altogether for England. The population of Great Britain is 35,000,000, of Austria-Hungary 40,000,000. "The directors do not give a formal estimate lest it may be thought exaggerated," but the little sum which they practically ask the investor to work out for himself is:—as 35 is to 40 so is £200,000 to the Austro-Hungarian Company's income. We do not remember to have seen any instance in which one worthless estimate has been so shamelessly built up on another equally worthless, and a conclusion suggested by so absurd a comparison. China has a population of 370,000,000. Investors should wait till the China Company comes out. They can see for themselves how much better their prospects will be.

Considerable prominence is, of course, given to the market value of other Elmore shares. The Foreign and Colonial Company is at a premium. There is no reminder that it might well be accounted for on the strength of the purchase price of the precious rights now parted with. The public should clearly understand that the price of Elmore shares is simply a measure of the reliance of the holders on the crop of latter-day fools, being sufficiently large to absorb more sub-companies.

There is little else in the prospectus beyond such useless announcements as that the Managing Director and Mr. Stepney Rawson are now taking a trip in Austria (doubtless at the company's expense) engaged in the selection of a site for the company's works, and that the arrangements generally have been carried through by Woodhouse and Rawson United, Limited, who floated the French Company, and whose valuable co-operation is secured in the organisation of this company. We have tried to discover what this ambiguous statement means, but without success. We fail to see why an investor should be grateful to Woodhouse and Rawson, United, for making arrangements whereby he should join in paying away £137,500, mostly in gold, and expend some more gold in the working of a process which may or may not deposit some coppers in his pocket in return. Nor do we see how their continued co-operation is to be made so valuable—to the investor.

We have before expressed our wish for something in the way of definite information on the Elmore process. We have also commented on some of Woodhouse and Rawson United company promotions. We regret that we are now compelled to repeat our warnings and to again draw attention to the disadvantage which the electrical profession incurs by such proceedings. We must perforce assume that Messrs. Woodhouse and Rawson United and the directors of the Elmore Company are persuaded (or persuade themselves) that the invention is valuable and the process economically workable, but it is not easy to characterise in safe language the conduct of those who continue to foist upon a public necessarily ignorant of its technical value a series of companies for the development of an unproved industry. The game, as we have already remarked, has been played before, and doubtless will be played again when another crop of fools shall have become ripe for it; but at least we hope the electrical industry will not be the foundation upon which such a terrace of unhealthy tenements will be built.

It is too late to stop the transfer of cash from the pockets of the public to those of the promoters. That has already been done to a large extent, and the present company, of course, like all its predecessors, closes its subscription lists before the publication of the technical journals. But there is one direction in which good money may be prevented being thrown after bad, and we earnestly press it upon the consideration of Elmore shareholders. It is a distressing incident in this process of company manufacture that sites have to be selected (and paid for), factories built, and machinery purchased, staff engaged, and wages paid.

We cannot too often reiterate that there is no proof of the commercial value of the process. If there were such proof, it is extremely unlikely that there is work enough for a tube factory and a wire factory in England, and factories elsewhere in every country in the world. We will confine ourselves to saying that the possible waste of money in this direction is a sad feature of the business, and we strongly commend the Austro-Hungarian shareholders to see to it that Lieut.-General Fraser and Mr. Stepney Rawson's selection of a site be

not confirmed, and that not one penny be devoted to the building of a factory until incontestable proof is forthcoming not merely that the process is practicable, but that Austria-Hungary offers a field of sufficient extent to justify manufacture on the spot, and further, to satisfy themselves that Austro-Hungarian Patent Laws, and Austro-Hungarian commerce give them a reasonable probability of fixity of tenure for any business they may start. The purchase money of the patents is a known sum. Let the waste stop there.

---

A RECENT issue of the *Wissens*  
The pathological effects  
of the Electric Light. *Wochenschrift* contains a short paper  
by a German medical authority upon

the pathological effects of the electric light. The glare of the electric light exercises a deleterious effect upon the eyesight of people who are exposed for too long a time to its action, and this effect is proportional to the power of the lamp. It might be thought that the injurious effects of the electric light upon the eyes are due to the fact that this light contains a preponderance of chemical rays, violet and ultra-violet, but this is not the case, for the eyes are not similarly affected by illuminations of that character. According to the writer, the "tired" sensation in the optic nerve and the local inflammation which accompanies it, are both due to the fact that the luminous waves proceeding from a powerful electric lamp are of very great intensity. The general symptoms induced in the eyes of people who have been exposed to the glare of unprotected lamps for too long a time are:—(1) Transient irritability of the retina; (2) local inflammation; (3) tears and "flashing" of light before the eye; (4) incipient paralysis of the eye. Usually, people experience sensations which are analogous to those which are felt when particles of foreign matter are present beneath the eye-lid. In order to prevent the sight being permanently injured, it is necessary to adopt hygienic shades, though these do not act thoroughly in reducing the intensity of the luminous waves. Rest must be sought, and the pain relieved by the application of cold water compresses. When the pain is almost unbearable—a calamity frequently suffered by those who have been exposed for many hours per day and for some time to the glare of powerful lamps—a medical man may relieve it by the injection of cocaine and atropine. The French call this peculiar malady *coups de soleil electriques*.

---

A TELEGRAM from Florence says:—  
The Florence Electric  
Tramcar Accident. "When the Electric Railway Company

tried to recommence the running of cars after the recent fatal accidents an angry mob rained stones on the vehicles and threatened to kill the conductors. Such is the state of public feeling just now that it is thought the whole scheme will have to be abandoned. The guard who caused the first accident by, in a moment of tipsy recklessness, turning the brake the wrong way, is reported to be dying in prison." We trust that the excited state of the populace will soon give way to calmer reasoning, and that no such misfortune to the prospects of electric traction as that which now seems probable will result. Still, such fearful disasters as this, combined with the frequent fatalities from electric lighting circuits, will be made

the most of by those interested in opposition schemes. and the industry has already quite enough to contend against.

Killed by Electricity.

THE *Daily Graphic*, of Friday last, contained a notice of a fatal accident to a lineman in Omaha, who was instantly killed whilst engaged in cutting a wire. A Reuter's telegram on Saturday also announced two more deaths at Winchenden, Mass., the preceding day, through an electric wire (*sic*) coming into contact with an incandescent circuit. We suppose a high tension circuit crossed the other. At the present rate of fatalities it seems likely that this year will be a record in the States.

The Vaughan-Sherrin Battery.

ON the 28th May, 1884, Mr. Probert, the well-known Postal Telegraph expert, read a paper before the Society of Arts, on primary batteries. He stated that to liberate a horse-power hour of energy, a quantity of zinc must be oxidised equal to 2.022 lbs. divided by the electromotive force of the galvanic couple in use. As this is theoretically the minimum consumption, we do not usually expect to find a battery in practice giving results somewhat better than is actually possible, and yet this is what Prof. Silvanus Thompson practically shows to have been obtained in his tests of the Vaughan-Sherrin primary cell. It is possible that his voltage readings were not quite accurate, and that the weight of zinc consumed was understated; nevertheless, we are face to face with an impossibility; and this shows the uselessness of giving a report on the strength of the laboratory performance of one element. With eight or ten cells a small error of observation would have made but little practical difference; with one, a trifling mistake proves fatal, for 2.022 divided by 1.99 gives one lb. and one quarter of an ounce as the theoretical demand, instead of one lb. and a fortieth of an ounce which the Professor claims to have actually obtained in his laboratory. Even if the newer determination of 1.995 mentioned in Kempe's "Electrical Engineer's Pocket-book," and credited, we believe, to Sir William Thomson, is taken, the actual consumption is still less than the theoretical. It is hardly worth while to follow these tests any further, but we would like to ask Dr. Thompson on what he bases his estimate of 9d. to 10d. per Board of Trade unit as the net cost of electrical energy drawn from this battery? Mr. Probert showed very conclusively that to produce 12.5 horse-power hours in the most economical manner necessitated for materials alone, an expenditure of 8s. 3d., or deducting 1s. 2½d. for sulphuric acid, which apparently is not used in the Vaughan-Sherrin element (unless as part of the depolariser), say 7s. Now this means theoretically 6½d. per horse-power hour, or 9d. per Board of Trade unit. How, then, can Prof. Thompson's estimate of *net* cost, which if it means anything is held to be clear of all deductions, be reconciled with these figures? There might be one explanation and that is, that the depolariser costs little or nothing; but this cannot be so, or how account for the high E.M.F.? The Professor's opinion upon the motor seems based upon somewhat antiquated notions. We know of half H.P. motors of 70 per cent. efficiency, containing not more than 60 lbs. of dead weight per brake horse-power developed, so we fail to see anything special in the motor under consideration. The

tests credited to Mr. H. R. Kempe in his official capacity as a technical officer of the Postal Telegraphs are delightfully vague and apparently made to order. It will be noticed that the E.M.F. of the battery is not given, although we have reason to believe that it differs very considerably from Prof. Thompson's; the results, however, show that local action was not altogether a negligible quantity. Mr. Kempe's ideas of launch gearing and boats generally seem hazy. Surely he must be aware that the motor shaft should be coupled direct to the propeller, thus eliminating all gearing, and that every conceivable shape of craft is available, and has been tried by other electric launch builders. Why does Mr. Kempe consider that this battery is well adapted to motive-power purposes? Until we see the figures obtained in actual practice, say on a good spin with a bath chair or tricycle, we can only consider such data as that upon which we have commented as purely speculative and hypothetical. There is, however, a probability that these batteries may supplant the hired man for driving bath chairs, and if this turns out to be the case, there will be considerable demand for them at seaside resorts, judging from the number of interesting invalids always seen at these places. But whether an invalid could manipulate the apparatus unaided is quite another thing.

Candle Power.

AS is well known, the accurate measurement of the candle-power of a source of illumination is by no means an easy matter; but this is hardly an excuse for the continual exaggeration with which we meet with reference to the power of arc and incandescent lamps. Even the fact that the latter, when turned out fresh from the manufacturers hands have their full nominal candle-power, is misleading, as deterioration commences almost from the moment the lamps are run, and in a very short time, a building, which is stated to be lighted with so many lamps of a certain candle-power, can only justifiably be said to have that illumination at the outset. Allowing for breakages, &c., and the consequent eventual miscellaneous assortment of lamps of various ages which are grouped in a building, it is hardly an exaggeration we think to say that the actual is at least 25 per cent. below the nominal illumination.

Gas and Electricity.

THE *Gas World* in drawing attention to the exaggeration of the light value of electric lamps, says:—"It may be urged that the electrician cannot prevent this change (alluding to the deterioration of incandescent lamps), and that he is not, therefore, responsible for any deficiency in the light. Would such an excuse be of any avail with a gas company? Could it plead that the coal purchased was not of the quality anticipated, or, that through some defect in the apparatus, the photometric value of the light had fallen below a given standard?" To this, we answer, certainly not at the present day, when the deficiency of light is known to be preventable; but in the early days of gas excuses of the kind would have been perfectly justifiable, and could certainly not have been "laughed out of court," as the *Gas World* says. When electric illumination has had the experience of years, and its defects are better understood, then excuses will no longer avail.

## TRAMWAYS.

THE Americans are proud, and justly so, of the great growth of electric tramways and railways in the United States, and they are apt to sneer at the tardy introduction of electric traction into this country. The causes of this state of affairs have been frequently explained. Generally speaking, tramway companies, like railway companies, will not adopt any new system of locomotion until it has been demonstrated to be practically reliable, and to be superior to the existing methods of traction by horses or locomotives, as the case may be. Moreover, they do not care to run the risk of converting their present horse cars, or locomotives, into electric cars at their own expense, but rather regard at a distance the development of electric traction by the traction companies themselves; and, finally, they do not seem inclined to favour electric traction. It would therefore appear that electric traction companies must continue to "demonstrate" until they have shown that their systems are cheaper than those existing, when the tramway companies will commence to seriously consider the advisability of a change.

In the meantime it may be interesting if we give details regarding the tramways of this country, and of their cost of working. The latest obtainable returns of the tramway companies are to be found in *Duncan's Tramway Manual* for 1890. At the year ended 30th June, 1889, the total capital expended on tramway construction amounted to £13,664,591, the mileage of lines open to traffic being 949, as compared with 904 in the corresponding period of the previous year. The number of horses employed was 27,060, as against 25,832; of engines 539, as compared with 514; of cars, 3,645, as against 3,501; of passengers carried, 477,596,268, as compared with 428,996,045. The working expenses increased by 6·6 per cent., and the net receipts by 14·9 per cent. The ordinary working expenses of the principal companies are shown in the following table. By ordinary working expenses are implied traffic expenses, stables, general, law, and rates, but no allowances are made for repairs and renewal of track, corporation rent, mortgages, interest, &c. :—

Name of company.	Mileage.	Ordinary working expenses per car mile.
Belfast ... ..	15½	6·87d.
Dublin United ...	32	7·49d.
Edinburgh ... ..	18½	10·82d.
Glasgow ... ..	30	9·52d.
Liverpool ... ..	61½	8·00d.
London ... ..	21½	7·40d.
London Street ...	13½	8·88d.
North Metropolitan	41	8·55d.
South London ...	13½	8·00d.

It will be evident from the table that the working expenses per car mile are higher than those admitted at the meeting of the Tramway Institute referred to some time ago, namely, 6½d.; but the latter figure probably does not include stable expenses, general, law, and rates.

It may be mentioned that the Blackpool electric tramway is worked with a capital of £20,025. The miles run during the last financial year were 94,000, and the dividend paid 7 per cent. The Bessbrook and Newry Tramway Company has a capital of £10,000, and the last dividend paid was 4 per cent. No particulars are obtainable of the other experimental lines worked by electricity.

**Tenders for Electric Lighting.**—Contractors for electric lighting, steam, gas engine and boiler power, also for all kinds of lighting other than electricity, are required. Particulars from the Secretary of the Glasgow East End Industrial Exhibition, Mr. J. R. Chalmers, 133, St. Vincent Street, Glasgow.

THE VAUGHAN-SHERRIN SYSTEM OF  
ELECTRIC TRACTION.

THE so-called *new* primary batteries are again being prominently brought before the public. A few weeks ago the Parisians professed to be greatly interested in the performances of an electric tricycle invented by M. Million and which was to revolutionise electric traction by means of the employment of a new primary battery. This invention an English electrical engineer, Mr. J. Vaughan-Sherrin, of Ramsgate, has endeavoured to excel. He has not taken advantage of the facilities afforded for attracting public attention by the Thames embankment or the West End streets, but has contented himself with demonstrations of his inventions in that picturesque quarter known as Eagle Wharf Road, N. At No. 48 in that street the Vaughan-Sherrin Electrical Engineering Company, Limited, has taken temporary offices, and there one of our friends wended his way last week to witness the demonstrations.

There are on view a Bath chair, a tricycle, a wherry and a launch propelled by electricity. The main features of the inventions are a new primary battery and a special form of motor, but it is not easy to find any novelty in the make of the battery, or anything special in the motor.

The primary battery is of the two fluid type with sheet zinc and carbon. In each cell are three fixed carbons and two replaceable zincs. Very light plates are used, and the particular construction adopted permits these to be placed very close together, so that the internal resistance is very small. The outer cells are of gutta-percha, and in them are embedded the porous cells which surround the zincs. The liquid used in the inner cells is water, whilst that placed in the outer cells is a depolarising liquid of *special composition*, capable, it is said, of being produced at a low cost.

The E.M.F. is nearly two volts. The motor is a two-pole Gramme machine having the field magnets made in such a manner that while maintaining great mechanical strength it admits of very perfect lamination of the iron. When properly set there is no sparking at the commutator. Prof. Silvanus P. Thompson has conducted a series of tests of the performance of the battery. He states that :—

"In one of my tests one of these cells gave out a current of 8·75 ampères (average) for five consecutive hours, with an electromotive force (average) of 1·88 volts, although the cell was only about half filled at starting. In another more complete test a cell gave a discharge lasting rather more than nine hours, of an average strength of 6·5 ampères, the average electromotive force over the whole period being 1·99 volts. The amount of zinc consumed was only 73·1 grammes, being at the rate of 1·24 grammes per ampère hour. This demonstrates that the quantity of zinc consumed per (gross) electrical horse-power hour will be almost exactly 1 lb. and one-fortieth of an ounce. In a third and more elaborate test one of these cells gave a current of the average strength of 7·85 ampères for 9¼ hours; the average electromotive force over the whole discharge being 1·74 volts, of which 1·308 volts was available at the terminal as the working number of volts; the total quantity of current discharged was therefore about 72·6 ampère hours. The total evolution of power was 126·17 watt hours (or about equal to ⅙ of 1 horse-power for one hour), of which about 31·26 watt hours were expended upon the internal resistance of the cell, and 94·81 watt hours (or about ⅙ of 1 horse-power for one hour) were available for useful purposes. Eight such cells would furnish to the circuit the equivalent of 1 horse-power for one hour; for example, they would furnish a power equal to the tenth part of 1 horse-power for 10 hours.

"The quantity of zinc consumed during the 9¼ hours discharge was about 90 grammes, or a little less than ⅙ of a pound; and the quantity of depolarising fluid was about half a pint. There is very little smell from

these cells, and that only at the latter end of the discharge; in the discharge which lasted  $9\frac{1}{4}$  hours there was no smell of any kind for the first six hours. The efficiency of these cells when working at a discharge of about 8 ampères is about 75 per cent. Taking this figure and assuming that the motor used with the cells was appropriately constructed and adjusted to run at an efficiency of 60 per cent., it is clear that the total consumption of zinc for an actual nett mechanical output of 1 horse-power would be about 2 lbs. 14 ozs. per hour. Each cell, when filled, weighs  $6\frac{1}{2}$  lbs., and yields 11 ampère hours per lb. of gross weight; or at the rate of  $38\frac{1}{2}$  lbs. gross weight per gross horse-power of electrical output. I know of no battery, primary or secondary, which for a given gross weight of cell will yield as great an output. The economy of zinc is remarkable, the consumption being close to the theoretical limit. I estimate the net cost of electric energy from such cells at 9d. to 10d. per Board of Trade unit.

"The motor tested first by me weighs 40 lbs., and it is intended for an output of from half to three-quarters of a horse-power when placed in a launch or on a tricycle. To give out its full power it should be supplied with current at a pressure of 55 volts, when it runs at a speed of from 1,500 to 2,000 revolutions per minute, according to circumstances. In my tests the motor was mounted upon a special testing stand, and supplied with current from a dynamo-electric machine. The current and potential were respectively measured by means of an ampère-meter and a voltmeter of the ordinary standard type, and the mechanical efficiency was measured by comparing the amount of electric power applied to a motor with the output of which it was capable, as measured by its actual power exerted upon a mechanical brake or dynamometer. This brake consisted of a grooved iron wheel (keyed to the shaft of the motor) at the periphery of which was applied a cord of graduated breadth attached to pans for holding weights; this form of dynamometer being that devised by Ayrton and Perry. The speed was measured by a counter. In three experiments made the same day, the following results were obtained:—

"(1) Current, 14.5 ampères; pressure of supply, 36 volts; speed, 1,252 revs. per minute; torque on brake, 10.306 pound feet; total electrical horse-power supply to motor, 0.699; mechanical horse-power executed by motor, 0.3907; efficiency, 55.86 per cent.

"(2) Current, 18 ampères; pressure of supply, 46.5 volts; speed, 1,380 revs. per minute; torque on brake, 14.139 pound feet; electrical horse-power supplied to motor, 1.122; mechanical horse-power executed by motor, 0.591; efficiency, 52.63."

The third test gave an efficiency of 46.35 per cent. On another day four other tests were made, when efficiencies of 56.2 per cent., 52.9, 53.2, and 65 per cent. were obtained. The professor also states:—

"Considering the size and weight of this motor, and comparing its efficiency with that of the best motors of equal weight or equal power in the market, I consider the performance of Mr. Sherrin's motor very satisfactory. For so small a motor the power is high, being at the rate of one horse-power for only 62 lbs. of dead weight. The electrically-propelled Bath chair is fitted with one of Mr. Sherrin's smaller motors, and is driven by the current derived from ten of his cells. In a short run which I took in it, on unfavourable roads and in muddy weather, it ran at about six miles per hour on the level, and ascended a gradient of about one in eight at the rate of about two miles per hour. It was perfectly easy to manage, and the batteries gave no trouble either from spilling or fuming. I consider the electric chair a thoroughly practical and successful vehicle. Of the electrical tricycle I have made no trial pending certain alterations now in progress in its structure."

Mr. H. R. Kempe, of the Electrician's Department, General Post Office, has also tested the battery. He finds that during a four hours' continuous run, an average current of 8.856 ampères was taken from the battery, and that the consumption of zinc was under

7 per cent. in excess of the theoretical amount. He also states:—

"The efficiency of the battery with the mean current of 8.856 ampères was 65 per cent. This value, which is rather less than that obtained by Professor Thompson, practically confirms the tests taken by that gentleman, as the current taken out was in excess of that which was drawn in the test made by him. Had the battery been run with a lower current, the efficiency must have been proportionately increased. The drop of electromotive force at the end of the four hours' run amounted to 10 per cent., which is small, considering the small size of the cells and the heavy current drawn out. There was an entire absence of visible local action during the run, and the fumes given out were exceedingly slight."

A third report on the Bath chair has been furnished by Mr. P. Jensen, M.I.M.E.

It is claimed that the tricycle will travel at eight miles an hour, and that the Bath chair will run six miles an hour, and will, when the cells are fully charged, run for nine hours. At the demonstration last week, however, the tricycle, with full current switched on, travelled at six miles on the level, the Bath chair at about four miles, and the wherry at six miles an hour on the adjoining canal.

The Vaughan-Sherrin Electrical Engineering Company, Limited, is being formed with a capital of £25,000 to acquire the whole of the patents.

## BRITISH ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.—LEEDS, 1890.

### CONTRIBUTIONS TO THE MOLECULAR THEORY OF INDUCED MAGNETISM.

By J. A. EWING, F.R.S., Professor of Engineering in University College, Dundee.

(Read before Section A, September 5th, 1890.)

As the facts of induced magnetism become better known, increasing interest attaches to molecular theories and increasing difficulty attends the theories that are current. Weber's fundamental conception that the molecules of iron or nickel or cobalt are always magnets, and that the process of magnetising consists in turning them from many directions towards one direction, has been strongly confirmed by the now well-established fact that there is a true saturation value, a finite limit to the intensity of magnetism, which may be reached or very closely approached by using a strong magnetic force.\* Without going further back, to enquire (with Ampère) how the molecules come to be magnets, we may take this conception as the natural starting point of a theory. But when we go on to examine the conditions of constraint on the part of the rotatable molecules which have been suggested to make the theory square with what is known about permeability, about residual magnetism and other effects of magnetic hysteresis, about the effects of stress, of temperature, of mechanical vibration, and so forth, we find a mass of arbitrary assumptions which still leave the subject bristling with difficulties. Many of the phenomena suggest, for instance, the idea that there is a quasi-frictional resistance which opposes the turning of the molecular magnets; this notion lends itself well to account for the most obvious effects of magnetic hysteresis and the reduction of hysteresis by vibration. On the other hand, it conflicts with the fact that even the feeblest magnetic force induces some magnetism. My object in this paper is to refer to another (and not at all arbitrary) condition of constraint which not only suffices to explain all the phenomena of hysteresis without any notion of friction, but seems to have in it abundant capability to account for every complexity of magnetic quality.

In describing Weber's theory, Maxwell points out that, if each molecular magnet were perfectly free to turn, the slightest magnetic force would suffice to bring the molecules into complete parallelism, and thus to produce magnetic saturation. He continues:—"This, however, is not the case. The molecules do not turn with their axes parallel to the force, and this is either because each molecule is acted on by a force tending to preserve it in its original direction, or because an equivalent effect is produced by the mutual action of the entire system of molecules. Weber adopts the former of these suppositions as the simplest."<sup>†</sup>

\* Ewing and Low, *Phil. Trans.*, 1889, A, p. 221; see also H. E. J. G. du Bois, *Phil. Mag.*, April 1890.

† Maxwell, "Electricity and Magnetism," Vol. II., § 443.

Weber supposes a directing force to act in the original direction of the molecule's axis which continues to act as a restoring force in that direction after the molecule is disturbed. This assumed constraint is quite arbitrary; moreover, if it were the only constraint, there would be no residual magnetism when the deflecting force was withdrawn. Accordingly, Maxwell modifies Weber's theory by introducing the further assumption that when the angle of deflexion exceeds a certain limit the molecule begins to take permanent set. The development of this, however, does not agree well with the facts.

The alternative which is offered in the sentence I have quoted from Maxwell was not followed up by him, and seems to have been very generally overlooked, notwithstanding its obvious freedom from arbitrary assumption. Several writers, notably Wiedemann\* and Hughest, have recognised the inter-molecular magnetic forces by suggesting that the molecules, when unacted on by any magnetising force from outside, may form closed rings or chains, "so as to satisfy their mutual attraction by the shortest path."† But Wiedemann expressly postulates a frictional resistance to rotation, which will prevent this arrangement from being more than approximately attained, and which may be more or less overcome by vibration.§

I lately commented on the fact that soft iron and other magnetic metals (notably nickel under particular conditions of strain<sup>1</sup>) show a remarkably close approach to instability at certain stages in the magnetising or demagnetising process.<sup>2</sup> When the magnetic force reaches a particular value, the rate of change of magnetism with respect to change of force may become enormous. Referring to this in a paper which has just been published,<sup>3</sup> Mr. A. E. Kennelly has reverted to the idea of chains of magnetic molecules held together by the inter-molecular magnetic forces, and contends that when such a chain is ruptured by applying a sufficiently strong external magnetic force it will fall to pieces throughout, and the molecular magnets which compose the chain will take their alignment suddenly. He accordingly sketches what he calls a "chain-theory" of magnetisation and an adaptation of the theory of Hughes, in which, however, he postulates an elastic resistance to the rotation of the molecules in addition to the constraint afforded by their mutual magnetic forces. Mr. Kennelly's remarks are highly interesting and suggestive; but I do not think (for reasons which will appear immediately) that the notion of closed magnetic chains can be maintained as a general account of the molecular structure of unmagnetised iron.

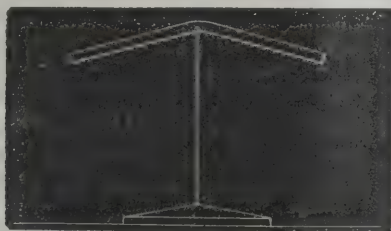

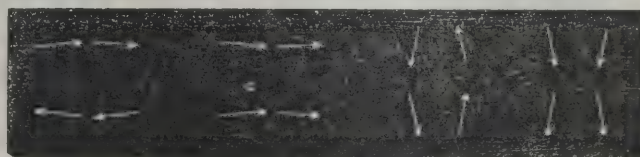

FIG. 1.

§ I have experimented on the subject by making a model molecular structure consisting of a large number of short steel bar-magnets, strongly magnetised, each pivoted like a compass-needle upon a sharp vertical centre and balanced to swing horizontally. We cannot readily imitate in a model the two degrees of rotational freedom possessed by the axes of actual molecular magnets, but a group of magnets swinging in one plane gives a sufficiently good general idea of the nature of the equilibrium which is brought about by inter-molecular forces, and the manner in which that equilibrium is disturbed when an external force is applied. The model is very easily made. Each magnet is a piece of steel wire about one-tenth of an inch in diameter and 2 inches long (fig. 1), bent in the middle to bring the centre of gravity below the point of support. The hole, or rather recess, for the pivot is made by a centre punch: the pivot itself is a sewing-needle fixed upright in a small base-plate which is punched out of a sheet of lead. The bars swing with but little friction, and their pole strength is sufficient to make the mutual forces quite mask the earth's directive force when they are set moderately near one another. The group is arranged on a board on which lines are drawn to facilitate regularity in grouping when that is wanted, and the board slips into a large frame or open-sided flat box wound round the top, bottom, and two sides, with a coil through which an adjustable current may be passed to expose the group to a nearly homogeneous external magnetic force. The coil is wound in a single very open layer, through which a sufficiently good view of the group inside

is obtained.\* A liquid rheostat with a sliding terminal is used to secure continuity in varying the magnetic force. It is scarcely necessary to add that the magnetic force which is applied to the group is too weak to have any material effect on the magnetism of individual bars. It alters their alignment only, just as a magnetic force alters the alignment of Weber's molecular magnets.

When a number of these magnets are grouped either in a regular pattern or at random, and are left after disturbance to come to rest free from external magnetic force, they of course assume a form which has no resultant magnetic moment, provided the number be sufficiently great; but it is apparent that they do not arrange themselves in closed chains. Any such configuration would in general be unstable. Many stable configurations admit of being formed, and if the magnets are again disturbed and left to settle, the chances are much against any one configuration immediately repeating itself. One general characteristic of these configurations is that they contain *lines* consisting of two, three, or more magnets, each member of a line being strongly controlled by its next neighbours in that line, but little influenced by neighbours which lie off the line on either side. Thus, if there are two magnets simply, they form (as might be anticipated) a highly stable pair, thus:—

if the inequality in distance be not too great. All these configurations are stable, and the condition of least energy, while making the first of them the most probable, does not prevent the occasional formation of the others. In a long line, the same condition leads in general to this formation:—

but it is by no means uncommon to find a line broken into two or more sections, thus :—

Seven magnets grouped so that the centres of six form a regular hexagon, with one in the middle, have a great variety of possible stable configurations, of which these are examples :—

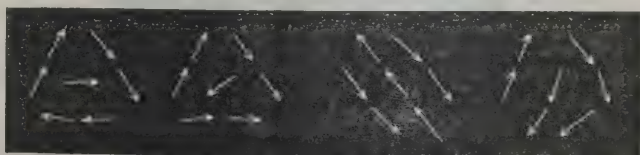

FIG. 2.

Experimental study of the forms which may be assumed by groups, and of the vibrations which may be transmitted through groups, is interesting, but to pursue it would be beside my present purpose. In all cases, the configuration assumed by a group is such that there is stability for small displacements, but different positions of the group may be stable in different degrees, and if members of the group be turned through a sufficiently great angle, they become unstable, and fall into a new position of stability, bringing about a partial reconstruction of the lines that characterise the group. Special interest attaches to square patterns, from the fact that iron and nickel (probably cobalt also) crystallise in the cubic system. In a square pattern of many members, we find, in general, lines running parallel with all sides of the square when the group settles without directive force after a disturbance.

Let the group, or collection of groups, be subjected to an external magnetic force,  $H$ , gradually increasing from zero. The first effect is to produce a *stable* deflexion of all members except those

\*\* *The Electrician*, June 7th and 13th, 1890.

which lie exactly along or opposite to the direction of  $\mathfrak{H}$ . This results in giving a small resultant moment to the group (assuming that there was none to begin with), which increases at a uniform or very nearly uniform rate as  $\mathfrak{H}$  increases. This corresponds to the first stage in the magnetisation of iron or other magnetic metal (a, fig. 3). The initial susceptibility is a small finite quantity, and it is sensibly uniform for very small values of  $\mathfrak{H}$ .

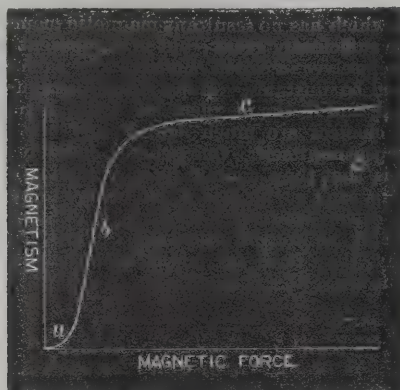

FIG. 3.

Suppose that, without going beyond this stage, we remove  $\mathfrak{H}$ ; the molecular magnets, not having been deflected beyond the limit of stability, simply return to their initial places, and there is no residual magnetism. This, again, agrees with the fact that no residual magnetism is produced by very feeble magnetising forces. Up to this point there has been no magnetic hysteresis. But let the value of  $\mathfrak{H}$  be increased until any part of the group becomes unstable, and hysteresis immediately comes into play. At the same time, there begins to be a marked augmentation of susceptibility—that is to say, a marked increase in the rate at which resultant moment is acquired. It is not difficult to arrange groups in which the state of instability is reached with one and the same value of  $\mathfrak{H}$  throughout the group. But, in general, we shall have different elementary magnets, or different lines of them, reaching instability with different values of  $\mathfrak{H}$ . The range of  $\mathfrak{H}$ , however, which suffices to bring about instability throughout the whole, or nearly the whole, of the members in most groups is not large; we, therefore, find in the action of the model a close analogy to the second stage (b, fig. 3) of the process of magnetisation, in which the magnetism rises more or less suddenly, as well as to the first stage (a).

During the second stage (b), the magnetic elements fall for the most part into lines which agree more or less exactly with the direction of  $\mathfrak{H}$ . If, at the end of this stage, we remove  $\mathfrak{H}$ , we find that a very large proportion of the moment which the group has acquired remains; in other words, there is a great deal of residual magnetism. To take an instance, suppose we have a group lying initially as in fig. 4, and apply a magnetic force,  $\mathfrak{H}$ , in the direction sketched, the first stage (a) deflects all the molecular magnets slightly, without making any of them become unstable; the second stage (b) brings the molecules into the general direction shown in fig. 5, or rather, that is the direction they assume when

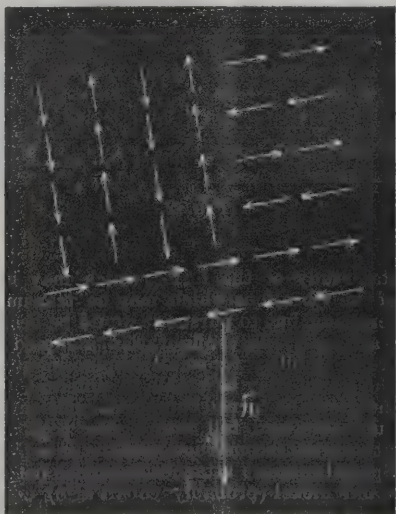

FIG. 4.

$\mathfrak{H}$  is removed, and the residual magnetism contributed by the group is then the sum of their moments resolved along  $\mathfrak{H}$ . When  $\mathfrak{H}$  is acting, the components along  $\mathfrak{H}$  are slightly greater, for the molecules are then (stably) deflected through a small angle towards the line of  $\mathfrak{H}$ .

Let  $\mathfrak{H}$  be further increased—we now have the third stage (c)

(fig. 3), which consists in the closer approach to saturation that is caused by the molecules being more nearly pulled into exact line with  $\mathfrak{H}$  (fig. 6). Whether there will be instability during the deflection of them from the lines of fig. 5 will depend on the closeness of the poles, and on the inclination of the lines of fig. 5 to the

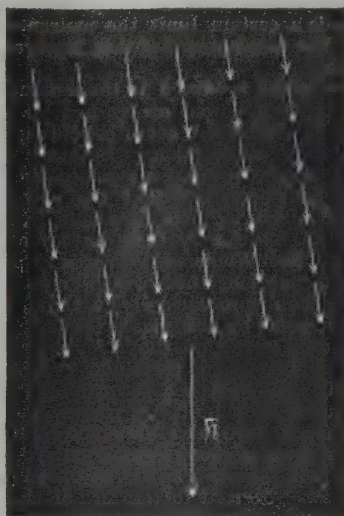

FIG. 5.

direction of  $\mathfrak{H}$  (see below). In some groups saturation will be complete with a finite value of  $\mathfrak{H}$ ; in others, it will only be closely approximated to. In magnetising any actual specimen of iron, we have, of course, to deal with a multitude of groups the lines to which lie at very various inclinations to  $\mathfrak{H}$ . If we remove the force  $\mathfrak{H}$  at a point in stage c, we find very little, if any, more residual magnetism than was found at the end of stage b. The ratio of residual to induced magnetism is a maximum about the end of stage b, and diminishes as stage c proceeds. This, again, agrees completely with the observed facts.

There is some hysteresis during the removal (whether complete or partial) and reapplication of magnetic force, because (provided we have enough groups to deal with) there will be some lines of elements which pass to and fro through a condition of instability during the removal and reapplication of the force. For certain inclinations of the line, the movements are not reversible.

Suppose, next, that having applied and removed a strong force,  $\mathfrak{H}$ , leaving strong residual polarity, we begin slowly to reverse  $\mathfrak{H}$ . At first, the effects are slight; presently, however, instability begins, and, as the force is increased within a narrow range, we find the molecules all upset. This is followed by a stage of nearly elastic deflection as saturation is approached. Thus, the well-known general characteristics of cyclic processes are all reproduced in the model (see fig. 8 below).

Again, a small repeated cyclic change of  $\mathfrak{H}$  superposed upon a constant value of  $\mathfrak{H}$  produces small changes of aggregate polarity, which are reversible if the change of  $\mathfrak{H}$  is very small. This, as Lord Rayleigh has shown,\* is what happens in a magnetic metal,

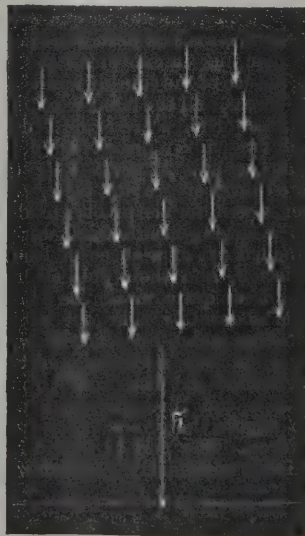

FIG. 6.

and the susceptibility with respect to small cyclic changes is small in the model, just as it is in the actual solid.

The chief facts of permeability and retentiveness, and hysteresis

\* Phil. Mag., March, 1887.

generally, are therefore at once explicable by supposing that Weber's molecular magnets are constrained by no other forces than those due to their own mutual magnetic attractions and repulsions. No arbitrary constraining forces are required. In the model the centres of rotation are fixed; in regard to the actual solid we may make an equivalent supposition, namely, that the distances between the molecular centres do not change (except in so far as they may be changed by strain).

Hysteresis, then, is not the result of any quasi-frictional resistance to molecular rotations; it occurs whenever a molecule turns from one stable position of rest to another through an unstable condition. When it is forced to return, it again passes through a condition of instability. This process, considered mechanically, is not reversible; the forces are different for the same displacement, going and coming, and there is dissipation of energy. In the model the energy thus expended sets the little bars swinging, and their swings take some time to subside. In the actual solid the energy which the molecular magnet loses as it swings through unstable positions generates eddy currents in surrounding matter. Let the magnets of the model be furnished with air-vanes to damp their swings, and the correspondence is complete.

A regular group of elementary magnets, especially when furnished with air-vanes, gives a good illustration of what has been called magnetic viscosity. When the imposed force  $\mathfrak{H}$  reaches a critical value one of the outer members of the group becomes unstable, and swings slowly round; its next neighbours, finding their stability weakened, follow suit, and the disturbance spreads through the group in a way eminently suggestive of those phenomena of time-lag in magnetisation which I have described in a former paper.\*

The model shows equally well other magnetic phenomena which presumably depend on the inertia of the molecules, such as the fact that a given force causes more magnetic induction when suddenly applied than when gradually applied, and leaves less residual magnetism when suddenly removed than when gradually removed.

The well-known effects of mechanical vibration in augmenting magnetic susceptibility and reducing retentiveness are readily explicable when we consider that vibration will cause periodic changes in the distances between molecular centres. This has not only a direct influence in making the molecular magnets respond more easily to changes of magnetic force by reducing their stability during the intervals when they recede from each other, but tends indirectly towards the same result by setting them swinging.

The effects of temperature which are common to the three magnetic metals may be stated thus:—Let any moderate magnetising force be applied, not strong enough to produce anything like an approach to magnetic saturation, and let the temperature be raised. Then the permeability *increases* until the temperature reaches a certain (high) critical value, at which, almost suddenly, there is an almost complete disappearance of magnetic equality. As regards the first effect, it is clear that an increase of permeability is to be expected from the theory; expansion with rise of temperature involves a separation of the molecular centres, and therefore a reduction of stability. As regards the almost sudden loss of susceptibility which occurs at a high temperature, it may do no harm to hazard a rather wild conjecture. We may suppose the molecular magnets to be swinging more or less, the violence of the swings increasing as the temperature rises, until finally it develops into rotation. Should this happen, all trace of polarity would of course disappear. The conjecture that the molecular magnets oscillate more and more as the temperature rises, is at least supported by the fact (carefully investigated by Hopkinson\* in iron and nickel; data for cobalt also have lately been supplied by du Bois†) that under strong magnetic forces rise of temperature reduces magnetism; for with strong forces the molecular magnets are already ranged so that their mean direction is nearly parallel to  $\mathfrak{H}$ : hence the earlier effect of heat (to diminish stability and facilitate alignment) does not tell, and the increased swinging simply results in reducing the mean value for each molecule of its moment resolved parallel to the magnetising force.

Before referring to effects of stress we may consider shortly the stability of a pair or line of magnets, treating each as a pair of poles subject to the law of inverse squares. Take first a single pair of equal magnets with centres at  $c$  and  $c'$  (fig. 7). The poles,  $p$ ,  $p'$ , would lie in the line  $c c'$ , but for the imposed force  $\mathfrak{H}$ , which produces a deflection,  $c c' p'$  or  $c' c p = \theta$ .

Let  $a$  be the angle which  $\mathfrak{H}$  makes with the line of centres,  $m$  the pole strength, and  $r$  the half length of the magnetic axis of each magnet. The deflecting moment is

$$2 \mathfrak{H} m r \sin (\alpha - \theta),$$

and the restoring moment is

$$\frac{m^2 c c N}{P P'^2},$$

$c N$  being drawn normal to  $P P'$ . The restoring moment at first increases with  $\theta$ , but passes a maximum at a value of  $\theta$  which depends on the relation of  $r$  to the distance between the centres. The condition of equilibrium is

$$2 \mathfrak{H} m r \sin (\alpha - \theta) = \frac{m^2 c c N}{P P'^2};$$

and as  $\mathfrak{H}$  and  $\theta$  are increased the equilibrium becomes neutral, that is to say, the condition of instability is reached, when

$$\frac{d}{d\theta} \{2 \mathfrak{H} m r \sin (\alpha - \theta)\} = \frac{d}{d\theta} \frac{m^2 c c N}{P P'^2}.$$

These two equations serve to determine the value of  $\mathfrak{H}$  and of  $\theta$  at which instability occurs. If we have to deal with a long line of magnets instead of a single pair, we have to write  $2 m^2$  instead of  $m^2$  in the restoring moment.

A considerable amount of stable deflection is possible when the distance between the poles is not small compared with  $r$ . When the direction of  $\mathfrak{H}$  is not much inclined to  $c c'$  (that is, when  $\alpha$  has a value approaching 0) there is no instability. In rows with various inclinations to  $\mathfrak{H}$ , the first to become unstable as  $\mathfrak{H}$  is increased will be that for which  $\alpha - \theta$  is equal to  $\frac{1}{2} \pi$ .

If  $a$ , the half distance between the poles in the undeflected position, be small compared with  $r$ , there is but little deflection before instability occurs, and in that case, provided  $a$  be not small, nor nearly equal to  $\pi$ , the occurrence of instability is defined by the condition

$$\frac{d}{d\theta} \frac{c N}{P P'^2} = 0,$$

which is satisfied when  $\tan \phi = \frac{1}{\sqrt{2}}$ ;  $\phi$  being the inclination of  $P P'$  to the line of centres. Hence, with the same proviso ( $a$  not nearly 0 or to  $\pi$ , and  $a$  small compared with  $r$ ), the value of  $\mathfrak{H}$  which causes the instability is

$$\mathfrak{H} = \frac{m}{12 \sqrt{3} \cdot a^2 \sin \alpha}$$

for a single pair of magnets, and twice this quantity for the middle members of a long row. This is, of course, least for magnets which lie normal to  $\mathfrak{H}$ .

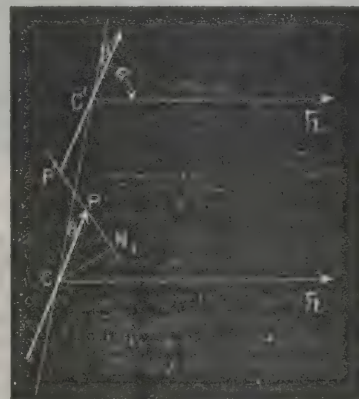

FIG. 7.

In the special case when  $\alpha = \pi$ , instability occurs when

$$\mathfrak{H} = \frac{m}{8 a^2}$$

with the single pair, or  $m/4 a^2$  with the row.

Applied to the case of a group of rows, uniform in distance between the centres, but various as regards their direction with respect to  $\mathfrak{H}$ , these considerations show that after  $\mathfrak{H}$  has reached a value sufficient to make the most susceptible members unstable, no very great increase is required to bring about instability in by far the greater number of the other rows. One general effect of increasing the distance between all the centres is to reduce the range of variation of  $\mathfrak{H}$  within which most of the different rows become unstable as the force is progressively increased.

In annealed metal, where we may expect considerable general homogeneity, as regards distance between the centres of the molecular magnets, we find that practically the whole of the abrupt stage in the process of magnetisation is included within narrow limits of magnetising force. We accordingly obtain curves like  $\Lambda$  (fig. 8).

When the metal is strained sufficiently to receive permanent set the curves take more rounded outlines (such as  $\Lambda B$ ), showing less susceptibility throughout, less residual magnetism, and more coercive force. The most natural explanation of this, on the basis of the molecular theory, appears to be that set produces on the whole a shortening of the distances between molecular centres, hence greater stability and more coercive force; but this is associated with heterogeneity, that is variety in the distances, hence the rounded outlines of the curves. We know that set tends to develop, or at least to emphasize, heterogeneity; for instance, a bar of iron or steel pulled in the testing machine stretches irregularly after the elastic limit is passed.

The effects of stress and consequent elastic strain on magnetic quality are so complex and so various in iron, nickel, and cobalt, that it would be premature to attempt any full discussion of them from the point of view of the theory now sketched. Only a few

\* "Roy. Soc. Proc.," June 1889.

† "Phil Mag.," April, 1890.

general features need be referred to at present. Some of these can be traced experimentally in the model by setting the supports of the magnets upon a sheet of thin India-rubber, which may be stretched or distorted to imitate the conditions of longitudinal or torsional strain.

When pulling stress is applied, those rows of molecular magnets which lie more or less along the direction of the stress, have their stability reduced by the lengthening of the lines of centres; similarly, rows which lie more or less normal to the stress have their stability increased. The resulting effect on the general susceptibility of the material will depend on which of these conflicting influences preponderates. Let pull be applied before magnetisation begins, while the metal is still in a neutral state. The stretching of longitudinal lines and the contraction of transverse lines will not only alter the stability of those molecules which continue to lie in their original rows, but will tend to make the members of those rows which are much lengthened swing round and form transverse lines in which they will be more stable than before. We may therefore reasonably expect that the permeability with regard to strong fields will be reduced by pull, as it actually is both in iron and in nickel, though with regard to weak fields the permeability may be increased, as it is in iron.

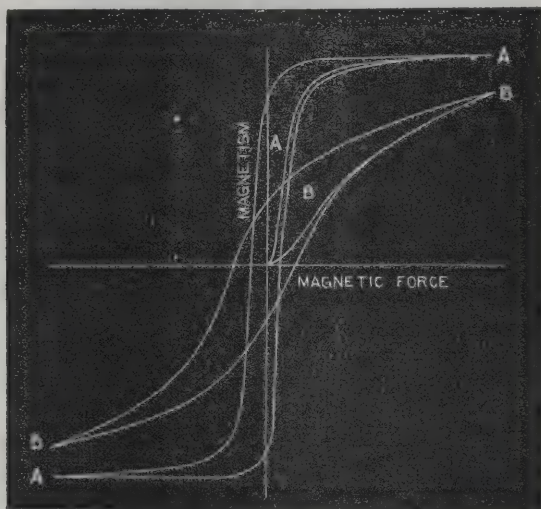

FIG. 8.

Again, the theory explains well why the effects of stress are by no means the same (1) when the stress is applied first and the magnetic force after, and (2) when the magnetic force is applied first and the stress after.

Let a moderate magnetising force be applied and then begin to apply stress. The first effects are in general large, for the strain precipitates into instability those molecular magnets which were already on the verge of instability. This is beautifully apparent in iron (see "Phil. Trans." 1885, part 2, plates 63 and 64); and the theory shows why the first effects are not reversible, why they do not disappear when the stress is removed, and why it is only in subsequent applications and removals of the stress that the magnetic changes become cyclic.

The same remark evidently applies to the first effects of stress on residual magnetism; also to the first effects of temperature-change either on induced or residual magnetism. Again, the theory shows that when a cyclic change of stress is repeated, there will be hysteresis in the corresponding changes of magnetism, whether induced or residual, unless either the cyclic range is very small or the magnetism approaches saturation. During each application of the stress, some molecular magnets will swing through unstable positions; during the removal of stress they will swing back, but not at the same values of stress. And it will be characteristic of this hysteresis that the variation in magnetism will begin slowly when the change from applying to removing stress, or from removing to applying stress, begins. All this agrees with the facts.

Moreover, the theory shows that even in the absence of any resultant magnetisation a cycle of stress makes the molecular configuration pass through a series of changes which will at first not be cyclic, but will become cyclic when the stress-cycle is repeated, and in which any intermediate value of the stress will be associated with different configurations during the going and coming parts of the process. In other words, we see that there will be hysteresis in the relation of molecular configuration to stress when a cycle of stress is repeated. Hence, certain rather obscure effects which have been observed in magnetic experiments; for instance, where an iron wire is loaded and partially unloaded down to a given load before being magnetised, its permeability is not the same as when the wire is completely unloaded and reloaded up to the same load. Experimental results of this kind led me in 1884 to write:—"If we apply and remove stress in a wire whose magnetic state is entirely neutral, we cause some kind of molecular displacement in the relation of which to the applied stress there is hysteresis."\* The

theory now offered shows how this happens. Hence, also, the remarkable hysteresis which the thermoelectric quality of iron exhibits with regard to cyclic changes of stress, discovered by Cohn, and more fully described in "Phil. Trans." 1886, p. 361. The hysteresis of molecular configuration with respect to stress has been proved to be removable or reducible by vibration.

From this theoretical explanation of hysteresis in the effects of stress, it at once follows that a cyclic change of stress (provided it be not very small) involves some dissipation of energy in a magnetic metal, whether the piece be magnetised or not. We may expect this dissipation to be most considerable under conditions which make the magnetic hysteresis large. But it will occur even when there is no external trace of magnetism.

This of course implies that, in a cyclic process of loading and unloading, work must be spent. There is no perfect elasticity in a magnetic metal, however slowly the process of straining be performed. Under any load there is less strain during application than during removal. This is borne out by experiments on the extension of iron wires (Brit. Assoc. Report, 1889, p. 502).

The same action occurs to a marked degree in torsional strains. In a twisted specimen there will be a tendency on the part of the molecular magnets to range themselves along lines agreeing more or less with the direction of maximum contraction. Alternate twisting to opposite sides should therefore cause much molecular swinging through unstable positions, with consequent dissipation of energy, even in a piece which is not magnetised.

Without going at present into details, it may be added that the phenomena of molecular "accommodation" studied by Wiedemann and by H. Tomlinson accord with the theory, and that it seems to lend itself well to explain the very remarkable results which have been obtained by Nagaoka\* in experiments with nickel wire under twist or under a combination of pull and twist. It also agrees with what little is known as to the influence that previous magnetisation in one direction has upon subsequent magnetisation in another direction.

To sum up, I have endeavoured to show:—

- (1) That in considering the magnetisation of iron and other magnetic metals to be caused by the turning of permanent molecular magnets, we may look simply to the magnetic forces which the molecular magnets exert on one another as the cause of their directional stability. There is no need to suppose the existence of any quasi-elastic directing force or of any quasi-fractional resistance to rotation.
- (2) That the intermolecular magnetic forces are sufficient to account for all the general characteristics of the process of magnetisation, including the variations of susceptibility which occur as the magnetising force is increased.
- (3) That the intermolecular magnetic forces are equally competent to account for the known facts of retentiveness and coercive force and the characteristics of cyclic magnetic processes.
- (4) That magnetic hysteresis and the dissipation of energy which hysteresis involves are due to molecular instability resulting from intermolecular magnetic actions, and are not due to anything in the nature of frictional resistance to the rotation of the molecular magnets.
- (5) That this theory is wide enough to admit explanation of the differences in magnetic quality which are shown by different substances or by the same substance in different states.
- (6) That it accounts in a general way for the known effects of vibration, of temperature, and of stress upon magnetic quality.
- (7) That in particular it accounts for the known fact that there is hysteresis in the relation of magnetism to stress.
- (8) That it further explains why there is, in magnetic metals, hysteresis in physical quality generally with respect to stress, apart from the existence of magnetisation.
- (9) That, in consequence, any (not very small) cycle of stress occurring in a magnetic metal involves dissipation of energy.

#### DISCUSSION.

Sir Wm. Thomson spoke of the extreme beauty and importance of the experiments shown by Prof. Ewing, and of the theory founded upon them. The fundamental idea of instability of the molecular magnetism seemed to be of very great importance indeed in explaining those puzzling phenomena which they had known in magnetic induction. The great amount of residual magnetism which Prof. Ewing himself showed to a higher degree than it had been shown before, was always one of the most difficult things to understand. But now that they saw an actual model in which those phenomena were produced, and in such an intelligible way, he thought that they might yet believe that the reality of the molecular constitution involved in a magnet was perfectly illustrated in that model. Who was to say that they had molecules pivoted round points? On the contrary, they were to believe more in the currents in cores theory, molecular currents. But they did not believe in magnetism as being merely translated from large models into a small scale to account for molecular phenomena. But he did say that if they had produced a model which illustrated any one part of the properties of matter, they had gone a certain distance towards explaining that property. What could be realised in steel and iron and wood and paper, was surely realisable in the wonderful and marvellous structure (let them not call it mechanism) of the molecule itself. They had numerous models to explain phenomena, but nothing he had seen had such

\* "Phil. Trans.," 1885, part ii., p. 614.

\* "Journal of the College of Science of the University of Tokio," vol. ii., 1888.

completeness as that they had been fortunate enough to see that day.

Mr. OSBORN REYNOLDS expressed his admiration for Prof. Ewing's work, and the happy discovery he had made of a simple process by which to illustrate a fact. Prof. Ewing said he thought friction had nothing to do with the phenomena of magnetism. But was Prof. Ewing prepared to say that that model had nothing to do with the explanation of friction just as it had to do with magnetism; and was there not a further step before them to explain friction by magnetism instead of magnetism by friction? It seemed to him that Professor Ewing had there an opportunity, not brought forward before in any way, of illustrating the action which for want of opportunity they lost. In an infinitely multiple system of positions of limited stability they had virtually a friction, and if they place it in any number of positions of limited stability it fell out of one to another. There they had it with very much more marked effect as regarded magnetisation.

Prof. FITZGERALD thought it would be very unfortunate if the general question were supposed to be confined merely to that of magnetisation.

Prof. EWING, in acknowledging the thanks of the section, said that for some years back he had been much impressed with the phenomenon, to which the name of hysteresis had been given, and as soon as this explanation of it occurred to him, it also seemed to him that the same thing had to be worked out in the way suggested by Prof. Reynolds and Prof. Fitzgerald as to friction.

Mr. MALLOCK (Torquay), said that Prof. Ewing had referred to the fact that there was a cyclic change in metals. He had experimented with many substances besides magnetic metals, and in only very few had he found anything like similarity between the first half the up side of the curve and the down side. Sapphire and topaz were very nearly the same, but he only noticed it in them.

## APPENDIX II.

### ON THE AIR CONDENSERS OF THE BRITISH ASSOCIATION.

By R. T. GLAZEBROOK (with a Note by Dr. A. MUIRHEAD).

(Presented in Section A, September 9th, in conjunction with the report of the Committee on Electrical Standards.)

THE question of issuing certificates of capacity has from time to time been discussed by the committee. The following paper gives an account of some experiments that have been in progress during the past two years with this object in view.

In the report for 1887 the committee express the opinion that it is desirable to proceed with the construction of an air condenser. In conformity with this opinion a meeting was held in London, at which Dr. A. Muirhead exhibited an air condenser consisting of a series of concentric brass cylinders insulated by glass rods, which appeared to the committee to possess great merits; and it was decided that the secretary should test this and two similar condensers which Dr. Muirhead offered to lend, before proceeding further with the construction of condensers for the Association. The tests were carried out with satisfactory results.

The capacity of each condenser was determined repeatedly, using the method of a vibrating commutator, due to Maxwell, already employed by J. J. Thomson, "Phil. Trans.," 1883, and Glazebrook, "Phil. Mag.," August, 1884. The values found were—

$C_1$	=	·0030514	microfarads.
$C_2$	=	·0031258	"
$C_3$	=	·0033288	"

It was found that the capacities remain constant from day to day, and that the accuracy of a single determination was about 1 in 1,000, although the capacity to be measured was so small.

A mica condenser belonging to the Cavendish Laboratory was compared with these—details of the method will be given shortly—and it was found that when comparing a condenser of 1 microfarad with the three air condensers combined, having thus a capacity of ·009506 microfarads, so that the ratio of the two was about 100 to 1, an accuracy of about 1 in 1,000 was attained. It was also shown that the capacity of the mica condensers as thus found, differed by nearly 2 per cent. from its value as determined by the rapid commutator, thus proving that the commutator method was unsuitable for a condenser showing absorption.

Thus for three mica condensers the following values were found:—

With commutator	By slow method of comparison.
·9690	·9868
·4934	·4994
·09543	·09644

These results make the necessity for an air standard all the more apparent. A report on the experiments, made up to that date, was laid before the committee at a meeting in London, in April, 1889. It was then decided to adopt Dr. Muirhead's form of condenser, and to have two made on the same pattern for the Association. These have been constructed by the Cambridge Scientific Instrument Company, following Dr. Muirhead's plan, but on an enlarged scale. Each has a capacity of about ·02

microfarads, or about six times that of one of the original condensers.

Fig. 1 shows the arrangement.

The condensers consist of 24 concentric tubes; the outer tube is about 2 feet 9 inches high and 6 inches in diameter. Each succeeding tube diminishes in diameter by half-an-inch; the tubes are about  $\frac{1}{32}$  inch in thickness, and the air space between the inside of one tube and the outside of the next is about  $\frac{1}{32}$  inch, but it was found impossible to get all the tubes of exactly the same thickness, so that in some cases the distance between the tubes is less than the above. These tubes are carried by two conical brass castings; the outside surface of each casting forms a series of twelve steps, over which the successive tubes fit. Each tube is held in position by screws. The upper cone is supported by the outside casing of the condenser, and twelve of the tubes hang vertically from it. The lower cone is carried by three ebonite pillars, about 3 inches in height; the twelve tubes which are attached to it come respectively between those which are suspended from the upper cone. Thus the insulation depends on the ebonite pillars, assuming there is no leakage across the air from the edges of the tubes. There is an opening in the outer casing, closed by a door, by means of which the ebonite can be cleaned; the whole is dried by placing inside a small vessel

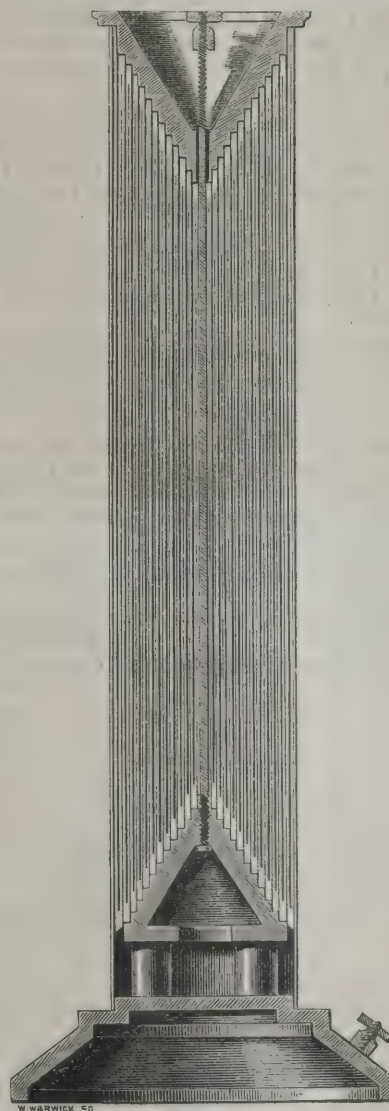

FIG. 1.

of sulphuric acid. In the centre of the upper cone there is a hole through which a rod passes. The rod is connected with the lower cone and forms the electrode for the insulated cylinders. An ebonite plug, fitting tightly round the rod, can be pushed down so as to close the hole and prevent the ingress of dust when the condensers are not in use; when they are being used the plug is removed.

The condensers are placed in the testing room at the Cavendish Laboratory and covered by a wood and canvas case to protect them from dust. It is not intended that they should be movable.

After this description of the condensers we will proceed to an account of the tests to which they have been subject. The first test was for leakage.

One set of cylinders was put to the earth while the other was connected with a gold leaf electroscope. An attempt was then made to charge them with an electrophorus or a small electrical machine, but this failed entirely. The electricity either sparked across at places where the tubes were very close together, or

before the potential rose sufficiently to affect the electroscope small fibres or dust particles which adhered to the tubes formed leaks across; it was clear that the condenser could not be charged to the potential of the machine. Tests were then applied for leakage when the potential was lower. One set of tubes were connected to one pole of a battery—about 36 storage cells were generally employed, having an E.M.F. of 75 volts—the other set being in connection with an insulated key, the second pole of the battery was connected through a galvanometer to the key and the condenser charged. After an interval, usually about 5 minutes, contact was again made at the key, the deflection of the galvanometer needle—assuming the E.M.F. of the battery not to have changed—was a measure of the quantity of electricity which had leaked from the condensers in the five minutes.

The amount of leakage was very different in the two condensers and depended greatly on the dryness of the air and ebonite pillars. Thus on March 11th, when strong acid had been enclosed for some time, for condenser I. the leak per 1 minute amounted to about .1 per cent. of the whole charge, while with condenser II. it was about 10 times as great.

The sulphuric acid was removed during the Easter vacation and replaced by calcium chloride and after this the leak in I. rose to about 1. per cent. per minute or 10 times its former value, while that in II. was from 3 to 4 per cent. of the charge. With the calcium chloride inside the leak was never reduced to less than about .8 per cent. per minute. In August the condensers having been closed since June with calcium chloride there was a leak in I. of about 3 per cent. per minute, while in the same time II. lost about 8 per cent. of its charge.

On August 14th, immediately after this test, the calcium chloride was replaced by sulphuric acid, and the leak was quickly reduced to about 1 per cent. per minute for I. For II., no improvement showed itself at once. The next day the leak in I. was about .4 per cent. per minute, that in II. had not been greatly reduced. On August 16th the ebonite was, therefore, well cleaned, and air was blown through the tubes of II., and the whole closed for about two hours; the leak had then fallen to about 2 per cent. per minute. By August 18th, the leaks were still more reduced, that in I. being .2 per cent. per minute, while that in II. was .6 per cent. per minute.

By the afternoon of this day, the upper parts of the condensers having been open to the air of the laboratory for some six hours during other tests, the leaks had appreciably increased, but they had fallen again the next day when the condensers were left closed during the night.

Thus, during the observations in August, with the exception of those on August 14th, the condenser I. was losing its charge at the rate of about  $\frac{1}{100}$ th part per 1 minute, while the leakage in II. was some five or six times as great, being about  $\frac{1}{10}$ th part of the charge per 1 minute.

As will be seen later, several mica condensers were compared with I. and II., the leaks in them were all small, and did not exceed more than  $\frac{1}{500}$ th per minute.

We come now to the experiments for determining the capacities of the two condensers. Of these, three independent series were made, viz., in December, 1889, May and June, 1890, and August, 1890.

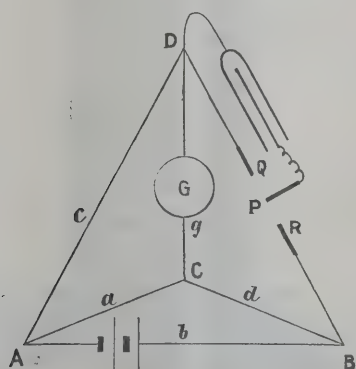

FIG. 2.

The method, already referred to, was used. Fig. 2 gives a diagram of the method; in fig. 3, the connexions actually employed are shown. With the notation employed, *Phil. Mag.*, August, 1884.

We have, if *c* be the capacity of the condenser, *n* the number of times it is charged per 1 second,

$$nc = \frac{a \left\{ 1 - \frac{a^2}{(a+c+g)(a+b+d)} \right\}}{c d \left\{ 1 + \frac{a g}{c(a+b+d)} \right\} \left\{ 1 + \frac{a g}{d(a+c+g)} \right\}}$$

In most of the experiments about to be described, we had the following values in legal ohms:—

$$a = 10 \quad d = 1,000 \\ b = 18 \quad g = 17,600$$

while *c*, which was the adjustable arm, varied from 6,000 to 15,000.

With these values, the only correction which need be included, is the last factor in the denominator, and we may write

$$nc = \frac{a}{c d \left\{ 1 + \frac{a g}{d(a+c+g)} \right\}}$$

The resistances were taken from a legal ohm box belonging to the laboratory; the various coils in this box were carefully compared with each other by Mr. Searle, and found to be consistent with each other, at any rate to within 1 in 10,000. The coils were also compared with the standards of the Association, and it was found that at 16° they were greater than legal ohms in the ratio of 1.0011 to 1. The standard temperature adopted in the experiments was 17°, and since the coefficient of increase of resistance of the box is about .0003 per 1° C., the resistances require to be multiplied by 1.0014, to reduce them to legal ohms. In some cases, in the value of *c*, coils from a B.A. unit box, containing coils of ten, twenty, thirty and forty thousand, B.A. units were employed.

The values found for these coils by myself in terms of the legal ohm box showed that they were very consistent with each other, and that the nominal 10,000 B.A.U. was equal to 9,880 legal ohms as measured by the legal ohm box.

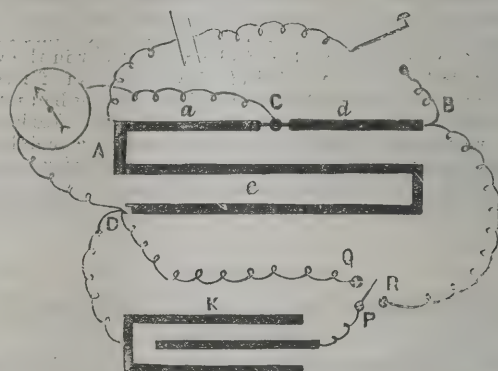

FIG. 3.

In the comparisons of two condensers certain coils from a megohm box were used; the value of each of these was also determined. They were as follows:—

1	...	98,731	Legal ohms of standard box.
2	...	98,625	" "
3	...	98,698	" "
4	...	98,735	" "
9	...	98,725	" "
10	...	98,776	" "

In the experiments on Dr. Muirhead's condensers, the vibrating commutator described in Prof. Thomson's paper, "*Phil. Trans.*,"

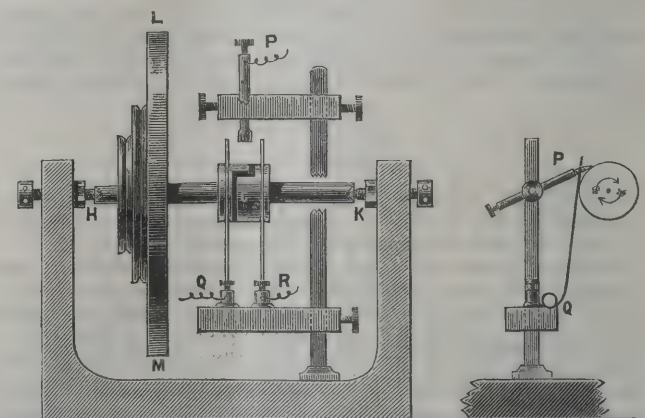

FIG. 4.

1883, or in my paper, "*Phil. Mag.*," 1884 was used, and that with complete success. In the experiments about to be described, this was replaced by a rotating commutator which had been fitted up by Prof. Thomson and Mr. Searle for their experiments on the other value of "*v*," and which possesses certain advantages over the other form. Dr. Muirhead and Dr. Fleming have also used a somewhat similar arrangement of apparatus. Fig. 4 shows the arrangement. The split ring commutator is carried on the axle, *h k*, which is driven by a water motor. Two wire springs, *q, r*, are in contact with the two halves of the commutator respectively, and as it rotates the brush, *p*, made of very fine brass wire, is brought into communication alternately with *q* and *r*. The disc, *L, M*, was of iron, and its mass helped to steady the motion. On one face of the disc a series of circles were drawn forming a number of annuli. The successive annuli were divided each into a different number of divisions by radial marks. Thus in the innermost annulus there were four on the next five, and so on.

The disc, as it rotated, was watched in the usual stroboscopic manner through two slits on two pieces of thin metal carried by the prongs of a tuning fork, which made about 64 vibrations per second.

When the frequencies of the disc and of the fork were in certain simple ratios to each other, the corresponding pattern on the disc was seen in a steady position. The driving pulley of the motor carried a second band, which passed over an idle pulley near the observer at the tuning fork, and the speed of the motor and hence of the disc was adjusted partly by varying the flow of water, partly by friction on this band until the desired pattern was seen in the steady position; this position was easily maintained by varying the friction on the string. The tuning fork drove a second fork an octave above itself in frequency. This fork was mounted near the standard fork of the Laboratory, and the beats between the two were counted. The frequency of the standard fork was determined by Prof. Thomson and Mr. Searle for their experiments on "v" recently communicated to the Royal Society. They found that it had changed slightly since it was determined by Lord Rayleigh, and give as the result of their experiments. Frequency at temperature  $t^{\circ}$

= 128.105 { 1 - (t - 16) .00011 }

The driven fork was always adjusted to a slightly lower frequency than that of the standard, so that there were about 20 beats to the minute between the two. During any series of observations 10 beats were repeatedly counted, but they rarely varied during the series sufficiently to affect the result. The commutator was designed and partly constructed by Mr. Searle, who observed at the tuning fork throughout. A little attention was required to secure good contact between the springs, q, r, and the rotating parts, and also to adjust the brush, p, but with moderate care in the adjustments the apparatus worked perfectly.

The galvanometer was one constructed in the laboratory; it had a resistance of 17,600 ohms, with a long silk fibre suspension—a quartz fibre would have been an improvement.

Its sensitiveness was such that 1 scale division corresponded to  $.83 \times 10^{-10}$  C.G.S. units of current; the time of swing was 7.2 seconds, so that the sudden discharge through the galvanometer of  $10^{-10}$  C.G.S. units of electricity produced a throw of one division, or, in other words, the quantity which, when discharged suddenly through, gave a throw of 8 divisions was  $8 \times 10^{-10}$ . This was determined by discharging through the galvanometer a condenser of capacity .1 microfarad when charged to 1 volt, the throw observed was 100 divisions, while the steady current due to an E.M.F. of .001 volt produced a deflection of 72 divisions.

The observations were made by varying c. There was a commutator in the battery circuit; in each position of this commutator two values of c were taken and the corresponding resting points of the spot on the scale observed. From these the value of c, which corresponded to the zero position of the spot, was obtained by interpolation.

These observations were made twice for each position of the commutator and the mean taken.

We will give one series as an example :—

August 27th, 1890.  
Temperature of standard fork 18.8°  
Beats ... .. 20 in 65.4 sec.  
" ... .. 20 in 65.2 sec.

CONDENSER No. I.  
Frequency, 80 approximately.

Position of Commutator.	Zero reading.	Resistance.	Resting point.
/	48	{ 5890	47
		{ 5880	51
\	48	{ 5880	46
		{ 5890	49
/	48	{ 5890	48
		{ 5880	51
\	49	{ 5880	46
		{ 5890	50

Temperature of coils 17.5°.  
Beats 20 in 64.8 at 19.3°.

It will be seen that between the third and fourth series the galvanometer zero has shifted slightly.

From these we get as the four values of c, the following :

5887.5  
5886.6  
5888.3  
5887.5

Mean 5887.5 at 17.5°  
Correction to 17° .9

Value c = 5888.4 at 17°

while the beats are 20 in 65 seconds at 19° or .307 per 1 second; at 19° the frequency of the standard is 128.066, thus the frequency of the driven fork is 128.066 - .307, i.e. 127.759. Thus for the driving fork we have the octave below this or 63.879, while the frequency of the commutator is 5/4 of this.

Hence in this series

$n = 79.849$   $c = 5888.4$

The accuracy attained in this series is a fair specimen of the whole. With these explanations we proceed to give the results in tabular form, showing the date, the values of n and c, and the resulting value of c. The wire by which the condenser was connected to the commutator together with the commutator itself, had a certain capacity which was determined in the same way, merely disconnecting the wire from the condenser. In the observations in December and June we found

$a = 10$   $d = 98730$   $c = 28460$   $n = 63.9$

whence the capacity of the wires is .0000625 microfarads, while in August after the apparatus had been set up afresh in a different position with new connecting wires, the value of c was 22,200 and the capacity .0000799 microfarads; for the wires the values of c could be determined to about 1 per cent.

In the table the value of c has been corrected for the capacity of the wires.

TABLE III., giving the capacity of two Mica condensers for various frequencies of charge.

CONDENSER A.

Frequency.	June 12.	June 14.	June 16.	Mean.
21	.04885	.04886	...	.04886
32	.04883	.04884	...	.04884
64	.04868	.04868	.04864	.04867
80	...	.04859	...	.04859

CONDENSER B.

21	...	.09642	...	.09642
32	...	.09642	...	.09642
64	...	.09634	.09642	.09638

Taking the air condensers first the tables show that at any rate for frequencies between 32 and 80 per second, the time of charging has no effect on the capacity, while the individual observations in each series are within 1 in 2,000 of each other.

For condenser I. the observations at frequency 64 are in all the series the least, but this is not the case with condenser II.

The capacity of condenser I. shows no change between December 1889 and June 1890. The observations in August 1890 are all rather greater than the earlier series but the increase about 1 in

2,000 is almost within the error of the experiments. With regard to condenser II. there is an indication of a rise in its capacity all through. It will be remembered that we have already shown that the insulation resistance of II. is considerably less than that of I. but it is easy to see that this leak was not sufficient to account for the change, for if  $R$  be the resistance of the leak, then our approximate formula becomes

$$n c + \frac{1}{R} = \frac{a}{c d} \text{ instead of } n c = \frac{a}{c d}$$

Now the current through the condenser when leaking most was about  $\cdot 0002 \text{ E c}$ , where  $E$  is the E.M.F. to which it is charged and  $c$  the capacity of the condenser.

Thus the resistance of the leak is  $\frac{1}{\cdot 0002 \times c}$  or  $\cdot 25 \times 10^{21} \text{ C.G.S. units}$ , since the value of  $c$  is  $\cdot 02 \times 10^{-15}$ . This resistance is 250,000 megohms.

Hence the correction to the capacity  $= 1/n R = \cdot 0002 \times c/n$ , and this is far too small to affect us.

There is no doubt then that the capacity of II. altered during the experiments by about 1 per cent. and it will be necessary to take it to pieces and set it up again.

It will be remembered that, in the early part of August, the leak in II. was very great, and it seems probable that the steps taken to discover the cause of the leak have produced a change in capacity. The experiments on II. then serve merely to show that the capacity can be found by the rotating commutator method to a high degree of accuracy, while those on I. prove that an air condenser, of  $\cdot 02$  microfarad capacity, has been constructed, which has retained its capacity, unaltered, for the eight months between January, 1889, and August, 1890.

The effect of the leak in condenser II., was still further investigated on August 28th. The plates of II. were connected by a resistance of 30 megohms. Hence the correction to  $c$ , which is

$$- \frac{1}{n R}, \text{ becomes } - \cdot 000520 \times 10^{-15}, \text{ when } n = 64.$$

The value of  $c$  found with the leak in was  $\cdot 023813 \times 10^{-15}$ .

Hence, making the correction,  $c = \cdot 02249$  microfarads, which is sufficiently close to the value found without the artificial leak.

Table III. shows that with mica condensers not very much greater in separate capacity than the air condensers, a change in the frequency of the charge from 21 to 80, produces an appreciable change in the capacity; this, of course, is in consequence of the absorption. With large condensers, as we have already seen, the effect is more marked.

It remains then to give an account of the experiments undertaken for the purpose of comparing mica or paraffin condensers, as ordinarily used with the air condensers, and of investigating some of the effects of absorption.

The two well-known methods of De Sauty and Sir William Thomson have both been employed.

The arrangements are shown in figs. 5 and 6.

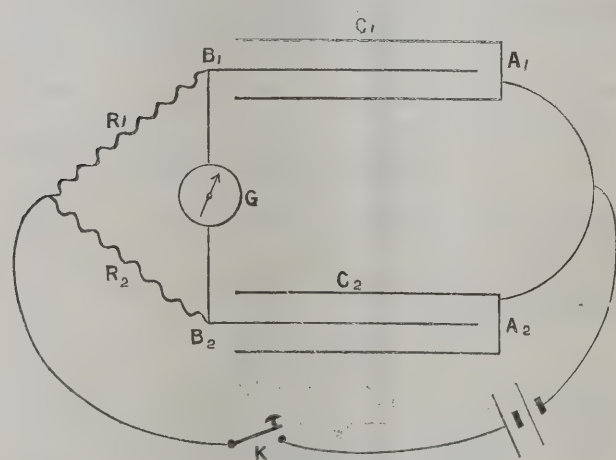

FIG. 5.

The first of these is not really suitable for use in cases in which there is absorption, though with care a fairly accurate measure of the instantaneous capacity can be found. The resistances,  $R_1, R_2$ , can always be arranged so that the effect of the charge rushing into the air condenser shows itself, as a sharp kick of the spot of light—to the left, say—followed by a slower deflection in the other direction due to the absorption charge soaking into the mica or paraffin. The resistance for which this sharp kick practically disappears is fairly definite, and from it the instantaneous capacity can be found, while an observation of the resulting kick due to the absorption enables us to calculate the increase of capacity which arises from that cause. This can be done in various ways; the simplest, perhaps, is to disconnect the condensers from the circuit, and replacing the mica condenser by a variable condenser of small capacity, observe the kick this produces in the galvanometer when charged with the same battery. From this the capacity to which the absorption is equivalent can be approximately calculated.

Thus a condenser of about  $\cdot 1$  microfarad was compared with

Dr. Muirhead's three condensers combined. Taking  $c_2, R_2$  to refer to the air condenser, we had

$$c_2 = \cdot 009506 \\ R_2 = 893650 \text{ ohms.}$$

and with  $R_1 = 89300$  there was a slight tremor to the left and a movement of three divisions to the right; on changing  $R_1$  by 100 ohms the change in the motion of the spot was marked.

This gives for the instantaneous capacity  $c_1 = \cdot 09550$ , the value found by the commutator at frequency 64 was  $\cdot 09543$  microfarads.

To evaluate the 5 divisions the air condenser was disconnected and the mica condenser replaced by one of capacity  $\cdot 001$  microfarads; the kick observed was 4.8 divisions, while with  $\cdot 002$  microfarads it was 9 divisions, thus a kick of 5 divisions corresponds to about  $\cdot 0011$  microfarad capacity. Hence the capacity of the mica condenser, including the full effect of absorption, is  $\cdot 0966$  microfarads.

The second method, about to be described, in which the absorption effect is included, gave  $\cdot 0965$  microfarads.

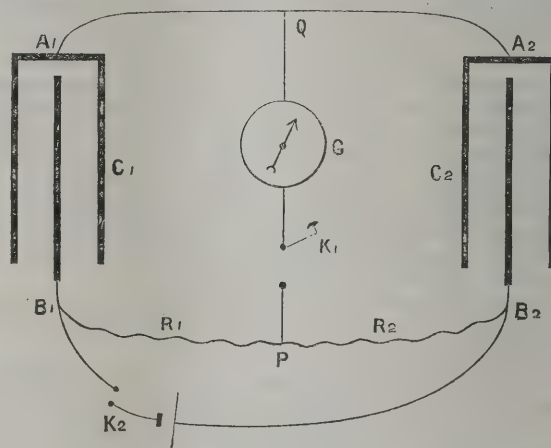

FIG. 6.

Let us now consider the second method. The current from a battery flows through a large resistance,  $R_1 + R_2, B_1 \text{ P } B_2$  (fig. 6). One plate of each condenser is in contact with  $B_1$  and  $B_2$  respectively, let  $v_1, v_2$  be the potentials at these points. The other plates,  $A_1, A_2$ , are insulated and connected together and to the galvanometer  $G$ , the other pole of the galvanometer can be connected to  $P$ , through the insulated key  $K_1$ . The galvanometer can be replaced by an electrometer. Let  $r_1$  be the resistance,  $P, B_1, B_2$  the resistance,  $P, B_2$ . Suppose the point,  $P$ , be put to earth, the rest of the circuit being insulated. Then if  $c_1, c_2$ , be the capacities it is easy to see that there will be no current through the galvanometer on making the key  $K_1$ , if  $c_1 R_1 = c_2 R_2$ .

Now in the case of a mica or paraffin condenser the capacity is a function of the immediate past history of the condenser and different values will be found for the  $R_1, R_2$ , according to the time the charging has lasted. Dr. Muirhead, however, who uses the method largely has shown how to obtain the instantaneous capacity from the observations. His method is described in the following extract from a letter to myself.\* In the method as described, one pole of the battery is to earth instead of the point  $P$  of fig. 6.

Dr. Muirhead writes:—"I have  $\cdot 05$  microfarad nearly in air condensers, and a series of mica condensers of  $\cdot 1, \cdot 2, \cdot 3, \cdot 331$  (original  $1/3$ ) and  $\cdot 498$  (original  $\cdot 5$ ) mf. capacity, all enclosed in a double air-tight box to keep the temperature as uniform as possible. The capacity of these standards is determined periodically by both the tuning fork method (using a revolving com-

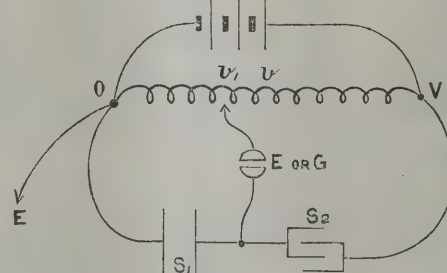

FIG. a.

mutator instead of the tuning fork), and by the ballistic galvanometer method. One can make comparison of these condensers among themselves and with other condensers by the method I adopt to an accuracy of 4 in 10,000. The temperature coefficient of shellacked mica condensers is about  $\cdot 018$  per degree centigrade and of paraffined mica  $\cdot 034$  per cent.

Let  $s_1$  be the capacity of the air condensers  
"  $s_2$  " " " " condenser to be compared with air  
condensers.

\* See also *Electrician*, September 5th, 1890.

After making battery contact, supposing the charging of the condensers to be instantaneous and the absorption nil, then we have

$$v s_1 = (v - v_1) s_2$$

where  $v$  is the potential of the junction of the two condensers. Should there be any delay in obtaining the balance, the position of  $v$  on the slides will vary—say to  $v_1$ —then the charges on the two condensers will be

$$v_1 s_1 \text{ and } (v - v_1) (s_2 + \sigma)$$

respectively where  $\sigma$  is the apparent increase of capacity of  $s_2$  due to absorption or soaking in of charge. On disconnecting the armature of  $s_2$  from the slides and putting it to  $o$ , or earth,

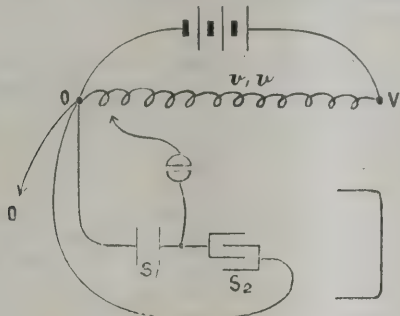

FIG. b.

the potential falls from  $v$  to  $o$ , and immediately afterwards the potential of the junction of the two condensers becomes, say,  $v_2$ , so that

$$s_1 v_1 + s_2 (v_1 - v) = (s_1 + s_2) v_2$$

Hence

$$v_1 (s_1 + s_2) - v s_2 = (s_1 + s_2) v_2$$

or

$$s_2 = s_1 \frac{v_1 - v_2}{v - (v_1 - v_2)}$$

$v$  and  $v_1$  are known, and  $v_2$  is indicated at once on an electrometer, or when a galvanometer is used it can be measured quickly thus:—As soon as  $v_1$  has been observed, break the galvanometer contact and move the index of the slides down to  $o$ , then directly after bringing the armature of  $s_2$  from the full potential of the slides to zero, close the galvanometer circuit and observe the throw,  $\alpha$ , which is a measure of  $v_2$ , the potential of the junction of the two condensers."

In my own experiments, which were made after consultation with Dr. Muirhead, I adopted a method practically the same as his; but before describing it, it will be better to consider rather more the effects of absorption. Let us suppose, at first, that the leakage from either condenser is inappreciable. If there be no absorption, each condenser is charged to its full potential practically instantaneously, and it does not matter when or in what order the keys,  $\kappa_1 \kappa_2$ , are put down, the position of  $p$  on the slide is not affected.

Suppose, now, that  $c_1$  shows absorption, the capacity increases with the time of charging. We can get the instantaneous capacity by depressing, first, the key  $\kappa_1$  and then  $\kappa_2$ , but in this case we are troubled with the effect of the slow after charging as in the other method. Still the resistance, for which the kick due to the initial charging disappears, is, with the condensers I employed, fairly marked, and a value for the instantaneous capacity can be thus fairly accurately obtained.

If, now,  $\kappa_2$  be made for 1 second and then  $\kappa_1$  depressed, a different position will be found for  $p$ . With this interval of charge the apparent capacity differs appreciably from its instantaneous value, and the after effects of the absorption can still be observed. The same is true for intervals of 2, 3 or 4 seconds, the value obtained for the capacity increases, and the after effect is still noticeable; but with the condensers and battery I used, if the time of charging was prolonged to 5 seconds, the after effect was inappreciable, and the position of  $p$  on the slide, and hence the apparent value of the capacity, were hardly affected by further increasing the time of charge. In the experiments on a cable recorded in Dr. Muirhead's paper already referred to, the absorption effects continue much longer. In the observations recorded below, then, unless the contrary is stated, the key,  $\kappa_2$ , was held down for 5 seconds, and then,  $\kappa_1$  being depressed, the position of  $p$  determined, for which the galvanometer remained unaffected. The value of the capacity deduced, then, is the full capacity for the potential to which the condenser is charged. It is of course possible, though further experiments would be wanted to prove it, that the full effect of absorption is not merely to increase by a definite amount, independent of the potential, the apparent instantaneous capacity, but that the increase may depend on the potential to which in each case the condenser is being charged. It will of course depend on the purposes for which the condenser is to be used whether the instantaneous capacity or the full capacity is required, and it probably will be best, when issuing certificates, to state both the instantaneous capacity and the maximum increase due to absorption—mentioning at the same time the potential used in the experiments for determining this correction, and also the time of charging in which this maximum increase is practically attained.

The method I employed in determining the correction due to absorption was the following:—Suppose the plates,  $A_1 A_2$ , to be at potential zero and uncharged. Make the battery key,  $\kappa_2$ , and after keeping it made for some little time break it again. If there be no absorption  $A_1$  and  $A_2$  will still be at zero potential and uncharged; but let there be absorption in one of the two,  $A_1$ , and let  $B_1$  be the positive pole of the battery; then, while the battery is on, negative electricity is being absorbed by the dielectric near  $A_1$ , and positive electricity is left free over the plates,  $A_1 A_2$ , and the wires connecting them. When the battery is broken the negative electricity begins to soak out, but the process takes time. Hence, if immediately on breaking the battery key,  $\kappa_2$ , the galvanometer key,  $\kappa_1$ , is made for an instant, there is a throw of the galvanometer needle indicating the passage to the earth of the positive set free by the absorption. If, after a time, the galvanometer key be again depressed, there is an equal throw in the opposite direction caused by the passage of the negative which has again soaked out of the condenser. The required correction is obtained from either of these throws.

For, let  $i$  be the current between  $B_1$  and  $B_2$ ; let  $c_1$  be the instantaneous capacity of the one condenser and  $c_2$  of the other; and let  $q$  be the quantity of electricity absorbed. Then the quantity of negative electricity on the plate,  $A_1$ , is  $c_1 R_1 i + q$ , and the quantity of positive electricity on the plate,  $A_2$ , is  $c_2 R_2 i$ , if we assume the potential of these plates to be still zero.

Therefore,

$$c_1 R_1 i + q = c_2 R_2 i$$

$$\therefore \frac{c_1}{c_2} = \frac{R_2}{R_1} - \frac{q}{c_2 R_1 i}$$

Then neglecting the battery resistance

$$i = \frac{E}{R_1 + R_2}$$

If  $E$  be the E.M.F. of the battery.

$$\therefore \frac{c_1}{c_2} = \frac{R_2}{R_1} - \frac{q}{c_2 E} \left( 1 + \frac{R_2}{R_1} \right)$$

Now, we have seen that with the galvanometer as I used it, if  $g$  is the throw produced by the passage of a quantity  $q$ , then  $q = 8 \times 10^{-10}$ .

The battery consisted of 36 small storage cells, which, when fully charged, had an E.M.F. of about 75 volts, so that

$$E = 75 \times 10^8.$$

Also,

$$c_2 = .021 \text{ microfarads} \\ = 21 \times 10^{-18}.$$

Hence, with these numbers,

$$\frac{c_1}{c_2} = \frac{R_2}{R_1} - \frac{8}{1575} \left( 1 + \frac{R_2}{R_1} \right)$$

Or, writing it as a correction to  $c_1$ ,

$$c_1 = \frac{c_2 R_2}{R_1} - \frac{8}{75} \left( 1 + \frac{R_2}{R_1} \right) 10^{-18}.$$

Examples of the method of applying this correction will be given shortly.

It will be noticed that a leak in one of the condensers may be corrected for in the same way. For, suppose the mica condenser to leak, then a quantity of  $q'$  of positive electricity passes through to the plate,  $A_1$ , while the battery current is on, and the condition that the galvanometer should not be deflected is,

$$c_2 R_2 i - c_1 R_1 i = q',$$

the same equation as previously.

There will, however, be this difference: on depressing the key,  $\kappa_1$ , after breaking the battery circuit, a positive charge will in both cases pass from  $A$  to  $B$  through the galvanometer; if this charge be due to absorption, there will, when the key is again depressed after an interval, be a current through the galvanometer in the opposite direction; while if the first charge be due entirely to a leak, there will be no effect when the key is the second time depressed. In practice, the leak and the absorption may exist together either in the same or different condensers. In the second case the leak will tend to produce opposite effects to those caused by the absorption; the quantity,  $q'$ , however, increases nearly in the ratio of the time of charging, while  $q$  increases for the first few seconds, but soon reaches a maximum and then remains constant.

These considerations are illustrated by some experiments in which the condensers I. and II. were compared with various mica condensers. The battery key was in each case made for 30 seconds; it was then broken, and the galvanometer key was made for an instant, the resulting throw was the sum of those due to (1) the leak in the mica condenser ( $\lambda$ ) say; (2) the absorption in that condenser ( $\alpha$ ) say; and (3) the leak in the air condenser, which produces an effect in the opposite direction  $-\lambda'$ , say.

After about 30 seconds more the key was again depressed, the resulting throw is due to the absorbed electricity which has again leaked out, and will give us  $-\alpha$ .

The following table gives the results; each observation entered is the mean of three or four.

TABLE.

Condenser compared with standard.	—	I.	II.
·05	$\lambda + a - \lambda^1$ — $a$	2·3 — 3	— 7·3 — 2·6
·1	$\lambda + a - \lambda^1$ — $a$	2·2 — 3	— 9 — 3
·1	$\lambda + a - \lambda^1$ — $a$	2·2 — 2·2	— 7 — 3·5
·5	$\gamma + a - \lambda^1$ — $a$	3·3 — 3·3	— 4 — 2·5
·1	$\lambda + a - \lambda^1$ — $a$	4 — 5	— 3·2 — 5·7

If we take the comparisons with condenser I. first, it appears that throughout  $\lambda - \lambda^1$  is small. For the ·05 and ·1 microfarad it may be about — ·5 divisions, while  $a$  is about 3 divisions; for the ·5 microfarad,  $a$  is rather larger being about 3·3 and  $\lambda - \lambda^1$  is zero, while for the 1 microfarad  $a$  the absorption effect is distinctly larger, being 5 divisions, and  $\lambda - \lambda^1$  is about — 1. All this is of course quite consistent with the fact that condenser I. and the mica condensers insulate well while there is absorption by the mica.

When, however, we come to the condenser II. the results are quite different. While the absorption effects are comparable, as of course they ought to be, with those obtained in the comparison with I. the leakage effects are very large.

The values of  $\lambda - \lambda^1$  in order are as follows, —9, —12, —10·5, —6·5, —8. Now we know that the mica condenser shows very little leak effect, the above leaks are therefore almost entirely in the air condenser II. If we suppose the total leak to be proportional to the time, then for the 5-second charges used in the experiments the corresponding values of  $\gamma$  in the corrections to be introduced for leakage will be 1/6 of the above, and thus we get the following results:—

Condensers.	Value of $\gamma$ .	Correction to capacity in microfarads for the leak.
·05	1·5	·00007
·1	2	·00016
·5	1	·0003
1·0	1	·0007

It is clear that the corrections are in all cases small, being not much over 1 in 1,000, but they serve to illustrate the method. The above corrections are only those for the leak, the correction for absorption could be found in the same way.

With a view to testing the method in a case in which a leak only existed without absorption, a number of comparisons of I. and II. were made.

In these experiments the resistance with I. was 296,240. The resistances with II. and the deflections due to the leak obtained by breaking the battery and then making the galvanometer, are given below together with the ratio of the two capacities corrected for the leak.

Interval between battery and galvanometer contacts.	Resistance.	Leak in scale divisions.	$\frac{R_1}{R_2}$	Correction.	$\frac{C_2}{C_1}$
0"	275,980	0	1·0734	0	1·0734
5"	275,180	2·5	1·0765	—·0032	1·0733
30"	271,380	14·5	1·0916	—·0184	1·0732
60"	267,180	22·5	1·1088	—·0286	1·0802
5"	91,370	5	4·3223	·0168	4·3391
30"	92,670	22	4·2617	·0743	4·3360
60"	94,170	42	4·1938	·1415	4·3353

The last three lines of the table give the results of a series of comparisons between II., which had a leak, and a condenser of ·1 microfarad, which showed absorption. The resistance with II. was 394,930 ohms.

In the first four lines the corrections are negative for the capacity of the leaky condenser is being found in terms of the standard. In the next three lines they are positive, for the ratio of the mica condenser to the leaky standard II., is being found.

A comparison of the fourth and sixth columns shows the results of the correction. In the fourth line it is clear that the correction is not large enough. This probably arises from the difficulty of making contact with the galvanometer circuit sufficiently soon after the battery is broken to ensure that the whole of the charge accumulated by the leak should pass through the galvanometer.

The leak correction was also tested with similar results by putting an artificial leak in I.

We will now give some specimens of the observations made to compare I. with a mica condenser in order to show the accuracy attained. Condenser I. compared with ·1 microfarad; resistance with I., 493,560 ohms; resistance with ·1 microfarad, 105,800 + a variable resistance given below.

In the table in which the effect of the galvanometer is shown by the letters R, L, in the last column, R means there was a deflection to the right, L to the left.

Interval between galvanometer and battery contact.	Variable resistance to be added above.	Effect on galvanometer.
5"	$\left\{ \begin{array}{l} 700 \\ 400 \\ 500 \end{array} \right.$	R L very small R
2"	$\left\{ \begin{array}{l} 400 \\ 700 \\ 600 \end{array} \right.$	L R L
0"	$\left\{ \begin{array}{l} 1200 \\ 1300 \\ 1400 \end{array} \right.$	L Tremor L, then swing to R R

Thus in this case the effect of an alteration of 100 in the resistance, i.e.,  $\frac{1}{1000}$  of the whole, is very marked, and we may take the following values for R:—

5" interval	...	105,800 + 500
2" "	...	105,800 + 650
0" "	...	105,800 + 1300

Other series of observations showed that the resistance for 10 seconds interval was the same as for 5 seconds; if the interval was prolonged to 30 seconds a very small increase in capacity was noticeable. Thus the effect of absorption is to increase the capacity of the ·1 microfarad by about 8 in 1,000, or ·008 of the whole, of this ·0065 shows itself in the first 2 seconds of charging and ·0015 afterwards, the increase after 5 seconds, if any, being extremely small.

When comparing I. with ·5 microfarad the resistances used were 592,290 and 24,910 respectively. In this case an alteration in the latter resistance of 10 ohms, or  $\frac{1}{2300}$ , was easily seen. The following are the results:—

Interval.	Resistance.
10"	24,900
5"	24,900
2"	24,930
0"	25,060

Showing again that the absorption effect disappears after 5 seconds, and that the effect of absorption in 2 seconds is about ·0052, and in 5 seconds about ·0064 of the whole capacity.

When comparing with 1 microfarad, the resistances were 592,290 and 12,580, the last number being accurate to about 5 ohms, or about the same proportion as before.

The results of the various observations are given in the following table, the observations made with II. have been corrected for the leak as already explained.

TABLE giving the capacities of certain mica condensers as compared with the air condensers.

Date.	Value from I.	Value from II.	Value found by commutator at frequency 64.
Aug. 19	·04934	·04938	·04867
23	·04934	·04936	
June 17	·09772	·09780	·09638
Aug. 14	·09751		
18	·09773	·09786	
21	·09773	·09781	
Aug. 18 (M)	·5005	·5008	
18 (A)	·5007	·5009	
21	·5006	·5010	
Aug. 18	·9910	·9912	
21	·9913	·9912	

It will be noticed that, for either condenser I. or II., the results are in very close accordance; with the exception of one observation, on August 14th, the differences are barely as great as 1 in

5,000, and the method is clearly capable of giving the value of a mica condenser in terms of the air condenser, to this accuracy.

The reason for the low result on August 14th, is to be found in the fact that, on that day, the leak in I. was considerable, being, as we have seen, over 1 per cent. per minute. Full observations for the correction were not taken; it would, however, amount to about '0002, judged by the correction required to observations on II., when leaking at a similar rate.

The results from II. are equally consistent among themselves, but all slightly greater than those from I. This would indicate that the correction applied for the leak in II. is rather too large.

The capacities given in the table are those found with a five seconds interval, by which time, as we have seen, the absorption on the mica condensers used is practically complete. We have already discussed the method of determining the instantaneous capacity, and a table of the corresponding values could easily be given.

For our present purpose it is hardly necessary to do this and indeed for many purposes for which condensers are employed, a knowledge of the full capacity is more useful than one of the instantaneous one. In the last column the values of the capacities found by the commutator method are given the differences in both cases amount to about 1.3 per cent. of the capacity.

During the forthcoming year condenser II. will be again set up and tested and the permanent arrangements for rapidly comparing condensers and for issuing certificates will, I hope, be completed.

The discussion on this paper and the whole of the series will be given next week.

### LONDON COUNTY COUNCIL.

THE Autumn Session was commenced on Tuesday last, Sir JOHN LUBBOCK in the chair.

The report of the Highways Committee stated the council, on the 29th July last, authorised the committee to deal, during the vacation, with any matter within the scope of their reference, which might require immediate action on behalf of the council. Acting under this authority, they have considered the undermentioned notices under the Electric Lighting Orders and Acts, and have, subject to the conditions stated below in each case, sanctioned, on behalf of the council, the works referred to therein.

Notice, dated 25th July, 1890, from the Notting Hill Electric Lighting Company, of intention to lay mains on the west side of Aubrey Road, from Notting Hill Square to Aubrey House, was agreed to on condition that the company shall give three days' notice to the council's engineer before commencing the works.

Notice, dated 31st July, 1890, from the same company, of intention to lay mains in Victoria Gardens, Ladbroke Road, Horbury Crescent, and Kensington Park Road, in substitution for the works in those thoroughfares sanctioned by the council on 24th June last, on condition that the company shall give three days' notice to the council's engineer before commencing the work; that the cover stones of the culverts under 20 inches wide shall not be less than 2 inches thick, and of the wider culverts not less than 2½ inches; and that where the culverts cross the carriage way, there shall be at least 9 inches thickness of Portland cement concrete above the cover stones of the culvert, in addition to the road material.

Notice, dated 31st July, 1890, from the Westminster Electric Supply Corporation, of intention to lay mains in Eaton Square, Eaton Place, Chester Square, and Ebury Street. This notice is for an alteration of the route of the mains sanctioned by the council on 6th May last, the alteration being made to meet the wishes of the inhabitants of the locality. The company shall give three days' notice to the council's engineer before commencing the work: the mains shall be laid under the footways wherever it is found practicable to do so; and that the covers of the boxes to be used shall consist of iron frames, filled in with material to suit the paving.

Notice, dated 1st August, 1890, from the London Electric Supply Corporation, of intention to lay distributing mains in Great George Street, Princes Street and Victoria Street. That the company do give two days' notice to the council's engineer before commencing the work; that the mains shall be laid under the footway whenever it is found practicable to do so, and be kept at least 9 inches beneath the under side of the paving; and that where it is found necessary to lay the mains under the carriage-way, they shall be kept at least 9 inches below the concrete or the road material, as the case may be.

Notice, dated 31st July, 1890, from the St. James and Pall Mall Electric Light Company, under its order of 1890, of intention to lay mains in Burlington Gardens, Sackville Street, Swallow Street, Bury Street, St. James's Place, and part of Shaftesbury Avenue. On condition that a proper plan of the proposed works be supplied by the company before any of them are commenced; that the company do give two days' notice to the council's engineer before commencing the work in any street; that the mains in Shaftesbury Avenue be laid in the subway of that thoroughfare; that the positions to be occupied by the mains in the subway be subject to the approval of the engineer of the council, and that the work of placing them there be carried out to his satisfaction.

The committee also directed the clerk to give a formal notice to the company requiring it to lay the mains for Shaftesbury Avenue in the subway of that thoroughfare.

An application was also considered of the Westminster Electric Supply Corporation for sanction to the laying of a 9-inch wrought iron pipe (to be used as a water main) from Victoria Station to the company's premises in Eccleston Place, along Wilton Road, Buckingham Palace Road, Eccleston Street and Eccleston Place, as shown upon a plan submitted by the company, in addition to the electric mains in those thoroughfares sanctioned by the council on 1st April last. The laying of the pipe referred to was sanctioned on condition that it shall be laid at the same time as the mains already sanctioned for those thoroughfares.

The committee had to report that the electric testing station at Nos. 42 and 43, Cranbourne Street is approaching completion, and that they have arranged for Messrs. Hampton and Sons to supply the necessary furniture, fittings, blinds, &c., for the station, in accordance with an estimate submitted by that firm, for the sum of £169 9s. 9d. This expenditure was included in the estimate of £2,100 for apparatus and other necessary incidental expenses approved by the council on 3rd December last.

It was reported that Mr. J. Somers, who on 18th February last was appointed, at a salary of £2 a week to act as caretaker at the testing station, and to assist the inspector, has resigned his appointment. The committee have appointed a person, temporarily, to take charge of the premises until the end of the year; and will in due course submit to the council the name of a person for appointment as successor to Mr. Somers.

The council, on the 22nd of April last, authorised the continued employment in the engineer's department, until the first meeting after the recess, of a person, at a salary of £3 3s. a week, who has been since 25th February last assisting with the work connected with the business of which the committee has charge. The time referred to has now elapsed; but the engineer reports that the assistance is still necessary, in consequence of the large extent of the works being carried out in the public thoroughfares by the electric lighting companies, and of the extra work devolving upon the department in connection with the establishment of the electric testing station. The engineer also states that in order to cope with the work arising out of applications of tramway companies for sanction to the use of mechanical power, and also for the purpose of obtaining information and preparing a reliable plan of the existing tramways in London, in connection with the report on the subject prepared by the vice-chairman of the committee, he requires the assistance of a competent surveyor for a period of three months. They recommended "That the services of the temporary assistant now employed at a salary of £3 3s. a week in the engineer's department, be retained for a further period of three months, and that a competent surveyor be employed for the same period, at a salary not exceeding £4 4s. a week."

The committee have considered a notice, dated 18th August, 1890, from the Metropolitan Electric Supply Company, of intention to lay mains in Queen's Road and Gardens, Pickering Place and Terrace, Bishop's Road, Inverness Road, Place, and Terrace, Porchester Gardens, Terrace, and Place, Lower Porchester Street, Queensborough Terrace, James Street West, Gloucester Gardens, Square, Place, and Terrace, Leinster Street, Terrace, and Gardens, Craven Road, Hill, and Terrace, Craven Hill Gardens, Cleveland Square and Gardens, Westbourne Terrace, Crescent, and Street, Uxbridge Road, Upper Hyde Park Gardens and Street, Kensington Gardens Terrace, Sussex Terrace, Square, Place, and Gardens, Eastbourne Terrace, Spring Street, London Street, Stanley Street, Talbot Square and Street, Grand Junction Road, Cambridge Terrace, Street and Square, Norfolk Square and Crescent, Oxford Square and Terrace, Radnor Place, Sumer's Place, Southwick Crescent, Street, and Place, Upper Southwick Street, Hyde Park Street, Square, and Gardens, Albion Street, Connaught Square, Portsea Place, Edgware Road, Albion Place, Upper Berkeley Place, Upper Seymour Street West, Stanhope Street and Place, Lancaster Gate, Street, and Terrace, Star Street, Charles Street, Charles Street West, Bathurst Street, Chester Place, Clarendon Place, Clifton Place, Devonshire Terrace, and Devonport Street (2 plans). This notice is in respect of an extensive area, but the proposed works are of the same description as those of the same company which have been sanctioned by the council on previous notices; and recommended: "That the sanction of the council be given to the works referred to in the notice (Registered No. 103) of the Metropolitan Electric Supply Company, dated 18th August, 1890, upon condition that the company give two days' notice to the council's engineer before commencing the works in any of the thoroughfares specified in the notice; that the mains be enclosed in 5-inch iron pipe, and be laid under the footways wherever it is found practicable to do so; that the covers of the boxes to be used shall consist of iron frames filled in with material to suit the paving; and that the works generally shall be of the description approved by the council on 1st October, 1889."

The following notices from the Notting Hill Electric Lighting Company were considered:—

August 20th, 1890, of intention to lay mains in Campden Hill Road; and to reduce the size of the culvert for the main in Campden Hill Gardens, already sanctioned by the council (1 plan).

23rd August, 1890, of intention to lay mains in Linden Gardens (1 plan).

5th September, 1890, of intention to lay pipes crossing High street, Notting Hill, Pembridge Gardens, Linden Grove and Dawson Place (1 plan).

22nd September, 1890, of intention to lay mains across Holland Park and Aubrey Road (1 plan).

24th September, 1890, of intention to lay a main on the east side of Pembroke Gardens (1 plan).

The proposed reduction in the size of the culvert in Campden Hill Gardens will be an advantage, inasmuch as the culvert will take up less space in the street; and the other works referred to in the notices are of the same character as those previously sanctioned by the council. The committee recommend: "That the sanction of the council be given to the works referred to in the notices (Registered Nos. 104, 105, 106, 107 and 108), dated 20th and 23rd August, and 5th, 22nd, and 24th September, 1890, respectively, of the Notting Hill Electric Lighting Company, upon condition that the company do give two days' notice to the council's engineer before commencing the work in any of the thoroughfares specified in the notices; that the cover stones of the culverts under 20 inches wide shall be not less than 2 inches thick, and of the wider culverts not less than 2½ inches; and that where the culverts cross the carriage-way, there shall be at least 9 inches thickness of Portland cement concrete above the cover-stones of the culvert, in addition to the road material."

The London Electric Supply Corporation has given a notice, dated 2nd September, 1890, of intention to lay trunk mains from Victoria Station (District Railway) across Buckingham Palace Road, and along Grosvenor Gardens to Ebury Street. The company has submitted a plan, which, in the opinion of the committee, is satisfactory, showing the manner in which the mains are to be protected from external injury; and there appears to be no objection to the proposed works, provided that the distributing mains for this route, for which notice has been given by the company (Registered No. 111), be laid, if possible, at the same time as the trunk mains. It was therefore recommended: "That the sanction of the council be given to the works referred to in the notice, dated 2nd September, 1890, of the London Electric Supply Corporation, upon condition that the company do give two days' notice to the council's engineer before commencing the works; that the mains be laid under the footways, and be kept two feet below the underside of the paving, wherever it is found practicable to do so; and that, if possible, the distributing mains for these thoroughfares be laid at the same time as the trunk mains."

The same company has also given the two notices under-mentioned:—

2nd September, 1890, of intention to lay distributing mains in Buckingham Palace Road, James Street, Little James Street, Buckingham Row, York Street, and Queen Anne's Gate.

3rd September, 1890, of intention to lay distributing mains in Knightsbridge Road, Wilton Place, Crescent and Road, Belgrave Square and Road, Upper and Lower Belgrave Streets, Hobart Place, Arabella Row, Grosvenor Place, Crescent and Gardens, Eaton Square and Place, Chesham Place, Lyall Street, Elizabeth Street, Chester Square, Eccleston Square and Street, Upper Eccleston Street, Ebury Street, Buckingham Palace Road, Eaton Lane North, St. George's Square and Warwick Square.

The committee, seeing no objection to the proposed works, recommend: "That the sanction of the council be given to the works referred to in the notices respectively, upon condition that the company do give two days' notice to the council's engineer before commencing the works in any of the thoroughfares specified in the notices; that the mains be laid under the footways, and be kept 9 inches below the underside of the pavement wherever it is found practicable to do so; and that where the mains cross carriage ways, they be kept at the same depth below the concrete or the road material, as the case may be."

The following notices of the Kensington and Knightsbridge Electric Lighting Company have also been considered:

3rd September, 1890, of intended extension in Montpelier Square, Rutland Gate, Cornwall Gardens, and Victoria Road (4 plans).

September 17th, 1890, of intended extensions in Young Street, and Exhibition Road (2 plans).

September 20th, 1890, of proposed extension in Queen's Gate Terrace (1 plan).

23rd September, of proposed extension in Cromwell Place (1 plan).

The works referred to in these notices are of the usual character, and it is recommended that the sanction of the council be given to the works referred to in the notices.

Notice dated September 4th, 1890, from the Chelsea Electricity Supply Company of intention to lay distributing mains in Bute Street, Sumner Place, Fulham Road, Alexander Square, Old Brompton Road, Onslow Square and Crescent, Pelham Street, Place, and Crescent, Thurloe Square, Alfred Place, East, South Street, Harrington Road, and road over Metropolitan Railway between Pelham Street and Thurloe Square (1 plan). The company states that the works will be carried out in the same manner as those previously approved by the council, but that it is not yet able to fix definitely the positions in which the various boxes are to be placed, received the sanction of the council on condition that a plan showing the positions to be occupied by the boxes, when decided upon, shall be submitted to the committee, and that the company do give two days' notice to the council's engineer before the works are commenced in any of the thoroughfares referred to in the notice.

The Westminster Electric Supply Corporation has given a notice, dated September 22nd, 1890, of intention to lay mains in Artillery Row, Old Rochester Row, Rochester Row, Great Peter Street, Vincent Square, and Churton Street. These works are such as have been approved by the council on former notices; but some of them will be in close proximity to the King's Scholar's Pond sewer, and the committee are of opinion that these should

be executed to the satisfaction of the council's engineer. The committee recommend: "That the sanction of the council be given to the works referred to in the notice on condition that the company do give two days' notice to the council's engineer before commencing the work; that the mains be laid under the footways wherever it is found practicable to do so; that the covers of the boxes to be used shall consist of iron frames, filled in with material to suit the paving; and that the works in the vicinity of the King's Scholar's Pond sewer be carried out to the satisfaction of the council's engineer."

The committee have considered a notice, dated August 27th, 1890, from Mr. H. Chadwick, on behalf of the Electricity Supply Corporation and Messrs. Gatti, of their intention to lay an electric cable along the Strand and Bedford Street. They were informed that the company has acquired, or is about to acquire, the right of lighting under the St. Martin's provisional order, 1889, and also the existing works of Messrs. Gatti, but that it is not clear that the necessary consents to such acquisition had yet been given. The committee have directed that further information be asked for; and pending the receipt of this, and having regard to the uncertainty as to the powers of the company, recommend: "That the council do give formal notice of disapproval of the works referred to in the notice (Registered No. 118), dated August 27th, 1890, of Mr. H. Chadwick, on behalf of the Electricity Supply Corporation and Messrs. Gatti."

The committee have, in accordance with the reference made to them by the council on 8th of July last, considered the following proposition by Mr. Leon: That inasmuch as many railway and other companies purpose making subways under "streets" in the County of London without paying compensation for such right of user, and whereas they will appropriate that property in the "streets" which is vested in the local authorities, and which may be required for the purpose of doing those things which commonly are done in or under the streets (such as subways and other works), the council resolves to recommend the local authorities not to consent to such user of the streets without compensation, and to petition Parliament against such Bills. That the Parliamentary Committee be instructed on all petitions of the council against Subway Railway Bills, to maintain the principle of compensation for such user, and assist as far as practicable any petitions presented by local authorities for that purpose. While agreeing with the principle of Mr. Leon's proposition, they were of opinion that it would be inexpedient for the council to pass any abstract resolution binding it to petition in a particular form in all cases, while the circumstances may be of infinite variety. When application is made to Parliament for compulsory powers to deal with the streets, the consent of the local authorities is not requisite if Parliament sees fit to grant the powers sought, but such bodies may, of course, oppose the granting of such powers. It was finally decided: "That it be an instruction to the Parliamentary Committee that, with reference to any railway or subway Bill for compulsory powers to carry out works under streets in the County of London, the committee do consider whether a petition should be presented against such Bill with a view to secure the insertion of proper provisions for payment of compensation to the public bodies in which such streets are vested, in respect of the beneficial user of the subsoil of such streets by the railway or other company or persons so using the same."

## REVIEWS.

*Screw Threads and Methods of producing them; with numerous Tables and complete directions for using Screw-Cutting Lathes.* By PAUL HASLACK. Third edition, rewritten and enlarged. London: Crosby, Lockwood & Son.

We are not surprised at the success which has attended this pocket-book, as it is extremely complete and concise. The work consists of seven chapters, dealing respectively with "Introductory Observations and Definitions," "Various Standard Screw Threads," "Plates, Die Stocks and Dies," "Screw-Cutting or Self-Acting Lathe," "Complex Rates and Hand Chasing," "Taps and Tap Making," "Tables of Screw Threads," &c. The importance of the subject of screw threads does not require enforcing, as it is almost self-evident; but how to practically deal with the question requires to be plainly set forth, as there are numerous points which have to be considered in order that the threads may be properly and easily formed. Examine under a magnifying glass the threads of screws cut by indifferently formed taps and dies, and the sight is not an attractive one, yet it is by no means difficult to so shape the taps and dies that the threads they cut are a pleasure to see. Anyone who carefully studies Mr. Hasluck's book shall have no difficulty in executing good work. As regards hardening and tempering, for example, we have the following precise instructions:—"Get plenty of water, such as a bucketful, add a hand-

ful of salt, and heat the taps one at a time in a clear fire till they are well red hot, but don't allow any of them to get hot enough to blister. When at the right heat stir round the water so as to make a small whirlpool in the bucket; take the tap and plunge it perpendicularly, threaded end first, quickly but steadily, into the centre of the whirlpool. If this is done carefully there will be little fear of the taps going out of shape, if they have been thoroughly annealed at least twice," &c.

*Journal of the Institution of Electrical Engineers.*  
No. 89, Vol. XIX. London: E. & F. N. Spon, 125, Strand.

The general contents of this number are as follows:—  
"On some chief features of the Edinburgh Exhibition, and mainly of the Electrical Section," by Prof. R. M. Walmsley; "Observations on Currents originating in ordinary Aerial Telegraph Conductors," by A. R. Bennett; "The Working Efficiency of Secondary Cells," by Prof. W. E. Ayrton; "On some Experiments in Radiometry," by A. R. Bennett; reply of Mr. K. L. Murray to the discussion on his paper "On the Lighting of the Centennial International Exhibition, Melbourne, 1888-89;" "A proposed system of Alarm Wires in Submarine Cables," by H. Kingsford.

*Water Purification for Manufacturers and Steam Users.* By SAWREY and COLLET.

This is a small book issued by the Stanhope Company, Limited, of patent telephone and water softener fame. The work is a very useful one, and of considerable value to those who have to deal with steam boilers, as the loss through scaling in the latter is often extremely heavy, being as much as 25 per cent. increase in the quantity of coal used when the scale is  $\frac{1}{8}$ th inch thick; this means about 22 pence extra per 1,000 gallons of water evaporated.

## ELECTRIC TRAMCAR SYNDICATE, LIMITED.

ON the afternoons of Tuesday and Thursday of this week, the Electric Tramcar Syndicate, Limited, who are working the Jarman patents, were enabled to run one of their new cars on the section of tram line between Clapham Common and Tooting. The London Tramways Company kindly gave the syndicate permission to use their line; but as the trips made by the electric car were sandwiched between those of the horse cars, apparently with a minimum of interruption to or interference with the ordinary traffic, and as each run was accomplished without a hitch or *contretemps* of any kind, we shall look forward to a time in the near future when these electrically-driven cars will take their regular place in the daily service between the above suburban districts. The road is well adapted for a tram line, being sufficiently wide for a double set of rails, with room on each side to allow carriages conveniently to pass. The gradients, for the most part, are not heavy, with the exception of a rise of 1 in 18 for a short distance, coming from Balham towards Clapham Common. The length of the line from the "Plough," High Street, Clapham, to the terminus at Tooting, is about two miles and a furlong.

In our issue of May 30th, 1890, we gave a full description of the car in an article entitled, "The Jarman System of Electric Traction." It will, therefore, suffice to briefly state that the car is of a similar pattern outwardly to the new two-horse tramcars, providing accommodation for 41 passengers, the outside being fitted with garden seats. The motor is double, the two armatures being carried on one spindle. The field magnets are wound on the "gamut" plan, to

facilitate the regulation of the motor and the consumption of power in proportion to the work to be done. The gearing consists of a single set of mortise wheels and pinions; the mortise wheels are of special construction, with vulcanised fibre teeth. The reduction in speed from the normal 650 revolutions per minute by the motor axle to 90 by the car wheels, provides for the propulsion of the car at the rate of between 7 and 8 miles per hour. This speed can be increased, when necessary, by using the full power of the motors in parallel to a maximum of about 16 miles per hour on the level. The motor and gearing are fixed to a steel frame attached to the axle boxes.

The driving arrangement is contained in a vertical case, enclosing a cylindrical commutator switch. By means of this switch all the manipulations requisite in working the car, whether for varying the speed, cutting off the current, or reversing the motor, are performed by turning one handle. Mr. Jarman has made a decided improvement by altering the position of the brake spindle, and placing it close alongside of the electrical switch; the brake handle is on a somewhat higher level than the driving one, to avoid the chance of any interference one with the other. The driver thus having both just under his hands should, certainly, derive some advantage in controlling the working of his car.

The battery of E.P.S. accumulators supplying the current to the motor consists of 52 double cells of the E type—19 plates in each cell—the whole coupled in series. The capacity of the cell is 140 ampère hours.

To enable the car to turn sharp curves, one of the wheels on the trailing axle is loose; this furnishes end play enough to allow the wheel base to accommodate itself to the different degrees of curvature to be found in the track usually laid down in this country.

The car which made the runs to Tooting was fitted with an ampèremeter and a Patterson and Cooper dead-beat magnet voltmeter, consequently we were able to take down a few readings to show the amount of electrical energy consumed during the journey. Of course, nothing more is shown than what may be termed the maxima and minima of consumption. The ground undulates, and some stretches on the road are worked by gravity alone; this applies in whichever direction the car is running.

The electric tramcar, with a full load of passengers, started from Clapham at 2.20 on Tuesday afternoon. The grade from thence is a gentle rise until the brow of the hill is reached above the down grade of 1 in 18; this steep declivity is of no great length, while the remainder of the distance to the fire station at Tooting is comparatively smooth, and only slightly variable. The journey was completed in 16 minutes; on the return, the time—including a wait to permit a horse-car to get a clear lead—was 19 minutes to Clapham. The second in and out journeys were accomplished in 18 and 16 minutes, respectively.

We append the actual time taken in running between certain landmarks on the road both going and returning. These figures exhibit what will prove to be the average time in which a distance of a little over 2 miles will be covered in everyday work where the general traffic may cause occasional delay.

### 1st Journey.

	h.	m.
Started from "Plough"	2	20
Cavendish Road	2	25
"George," Balham	2	27
Balham Station	2	33
Fire Station, Tooting	2	36

Total time, 16 min.

### Return.

	h.	m.
Leave Tooting	2	40
Balham Station	2	46
"George," Balham	2	54
Cavendish Road	2	56
"Plough," arrive	2	59

Total time, 19 min.

2nd Journey.

	h.	m.	
Started from "Plough"	3	3	
Cavendish Road ...	3	8	
"George," Balham ...	3	10	
Balham Station ...	3	15	
Fire Station, Tooting ...	3	21	
			Total time, 18 min.

The electrical power varied from 15 amperes at a pressure of 110 volts, to 50 amperes at 175 volts, with intervals when no current was required.

Return.

	h.	m.	
Leave Tooting. ...	3	38	
Balham Station ...	3	42	
"George," Balham ...	3	48	
Cavendish Road ...	3	50	
"Plough," arrive ...	3	54	
			Total time, 16 min.

The power consumed varied from 10 amperes at 120 volts, to 25 at 190. The gradient of 1 in 18 was negotiated at a slow speed with 50 amperes at a pressure of 90 volts; the run across Clapham Common being down hill, gravity did most of the work.

We understand that the officials of the Board of Trade are well satisfied with the working of the car, and the Jarman system generally. We also hear that the Electric Tramcar Syndicate has been requested by an influential firm in Spain to give it the option of introducing the system into that country.

NOTES.

**The Electric Light at Folkestone.**—After all the time and labour which the Folkestone Town Council have spent upon the question of lighting the town by electricity, the contract between them and Messrs. Crompton and Co. has been completely upset. It was stated at the last meeting of the corporation that the negotiations with Messrs. Crompton had cost something like £200, and it was strongly urged that the corporation should bring an action against the contractors to recover the money. The mayor was asked by Councillor Thompson to call a special meeting of the Electric Lighting Committee together in order that they might consider the advisability of taking proceedings, and the mayor promised to call it together at an early date. There can be no doubt that Messrs. Crompton & Co. will be very willing to contest the matter in a court of law; for after the treatment they received from the Folkestone corporation, they must be armed with every reason for their reluctance in carrying out their contract.

**The Electric Light at Exeter.**—At a meeting of the Town Council of Exeter, the special committee on Electric Lighting reported that they had received a letter from Mr. C. T. K. Roberts (solicitor to the Exeter Electric Light Company) enclosing two copies of the draft of the provisional order which the company intended applying for in the ensuing session. The draft was stated to be based on model order issued by the Board of Trade, and contained the latest modifications of such order. The committee, after considering the draft, were of opinion that the council should, in the interests of the citizens, itself apply for a provisional order to be confirmed by Parliament in the ensuing session for the supply of electricity within the city, and that the consent of the council should not be given to such an order being given to the Exeter Electric Light Company. After objection had been taken that the procedure suggested might involve an expenditure on the part of the council of possibly £30,000, it was decided to hold a special meeting to consider the matter.

**The Electric Light in Godalming.**—The Electric Lighting Commission, after visiting Bath, have reported favourably on the employment of electric light. It is intended to canvass the town to see if the majority of the inhabitants will support a scheme.

**Castleford and Street Lighting.**—The Local Board is asking for estimates for the lighting of the streets by electricity.

**Ship Lighting.**—The "Royal Steamship Packet Company" have just added to their fleet three or four large steamers, well equipped with electric lighting plant. The *Clyde*, the largest of the four, has an installation fitted by Siemens Brothers. The ship is wired on the single wire system, the ship giving the return. The dynamo is placed in the engine-room, and is driven by one of Tangye's vertical engines, coupled direct. At 200 revolutions the dynamos give an electromotive force of 115 volts with 220 amperes, and is sufficient to run 354 lights of 16 candle-power. There is a spare armature provided in case of breakdown. There are six main circuits, and throughout the ship are placed 36 ten-light distributing boxes. The principal advantage of the arrangement is that there are no joints in the system. From the one switch in the box the lights are controlled, and it is an easy matter to ascertain the position of any defect. Some of the lights are arranged to run independently of the switch, providing a night or police circuit. The rooms are all fitted with Edison-Swan lamps with frosted globes, and there are several cargo lamps of 4, 6, and 8 lights.

The ss. *Aranmore*, built for the Clyde Shipping Company, and intended for the South of England and South of Ireland trade, ran her trial trip on the Clyde on Saturday. The *Aranmore* has a complete installation of electric light in every part.

**Something Wrong.**—The *Standard*, on Tuesday, had a notice to the following effect:—"Owing to the interruption of telegraphic communication, we are this morning without a portion of our despatches from the Continent." Can it be that the Ferranti mains had anything to do with this interruption in the telegraphic service?

**Magdalen Islands Cables.**—We learn from the *Canadian Gazette* that the cable laid in 1880 between Cape Breton and Bird Rock, Gulf of St. Lawrence, is to be taken up and relaid to St. Paul's Islands. It is a coincidence that at the moment the cable is to be removed the daily journals should be discussing the sale of the Magdalen Islands to certain French capitalists.

**The Anticosti Cable.**—The Anticosti cable, just laid by Mr. Gisborne, commences at Mechestic Bay, Anticosti, and terminates at Tongue Pointe, on the north shore. The land lines to connect the cable with the existing telegraph system are being pushed forward, and, when completed, Anticosti will have cable communication with both shores of the gulf, and a land line round the south shore of the island, which has the reputation of being the graveyard of vessels. The cable referred to is 21 nautical miles in length, and was manufactured by the Silvertown Company. The laying was effected by the Government telegraph steamer *Newfield*.

**The Bahamas.**—In view of the success attending the more recent development of the fibre industry in the Bahamas, endeavours are being made to establish direct steam communication between Halifax and Nassau, and to subsidise steamers making the latter a port of call on the West Indian route. Steps are also being taken with the view of affording telegraphic facilities to the Bahamas by means of a cable between Nassau and Florida.

**Motors in Germany.**—The use of electro-motors in Germany is extending. Messrs. Ludwig, Löwe & Co., of Berlin, obtain current from the town electric light company's mains for driving the tools and machines in their workshops. The large steel works of Henkel, in Solingen, have an installation in which Lahmeyer dynamos and motors are employed. The whole of the works is lighted electrically, and the motors actuate 40 steel presses, lathes, and drilling machines. It is proposed to operate all the machinery by motors.

**Base-Ball Reporting.**—Reporters of cricket, football, tennis, &c., matches, must look to their electrical education, or the sporting journals they represent will be out of the hunt when compared with the enterprise and linguistic attainments shown by contributors to the technical Press. We select, as an example, a description of a base-ball match as reported in the columns of the *New York Electrical Engineer*:—"An exciting contest took place at Jackson Park, on Saturday last, between the Okonites and Kerites teams, composed, respectively, of the *employés* of the Central Electric Company and the Western Electric Company. The score was 21 to 6 in favour of the Kerites, and throughout the game their megohm capacity was never lowered in the slightest. The victors claim that their success was entirely due to the high insulation resistance they maintained. They short-circuited the bases in remarkable style, and no faults appeared, even under the high pressure current of the Okonites. The Okonites made a gallant struggle, but were unsuccessful in their endeavours to ground their opponents. The specific inductive capacity of both sides for hits of high voltage was enormous, and some fine work was witnessed by the numerous spectators, who said they had never seen a game so free from unnecessary retardation."

**The Advance in Rubber.**—The Gutta-Percha and Rubber Manufacturing Association of New York, at a meeting lately held, confirmed the advance of 10 per cent. on rubber goods made at the previous meeting. Prices of crude rubber had advanced 5 per cent., and some kinds were very scarce. The output from Brazil was as large this year as formerly, but the demand, both in the States and Europe, had increased enormously. It was announced that there would not be any further rise in the price of manufactured rubber for at least a month.

**Remedy for Vibration.**—It is said that felt made from hair, placed in the foundations of engines, effectively remedies the noise and vibration so often a cause of complaint. An electric company recently removed one of its 90 H.P. engines from its foundations, which were taken up to the depth of 4 feet. A layer of hair-felt, to the thickness of 5 inches, was then laid down, and run up round the sides to the height of 2 feet. The brickwork was then built up on the top of this.

**New Insulating Materials.**—Messrs. Alexander, Barney and Chapin, of New York, have introduced a new insulating material called "alexite." It can be made into any shape, and has the qualities necessary for cut-outs, switches, &c., being water, fire, and acid proof. Any colour of wood, paper, or marble can be closely imitated, so that, for interior wiring, harmony with the general upholstery can be maintained.

We have noticed in American technical journals very favourable reports as to the qualities of "fibrone" as an insulating material. It is a solid and plastic substance, said to present many of the most desirable characteristics of rubber. It is stated to be a perfect non-conductor, to be absolutely waterproof, and able to resist the weaker acids. It can be sawn, planed, drilled, tapped, or turned in a lathe, can be given delicate and bright colours, and can be made to represent natural woods, marble, stone, and metals. Under ordinary temperatures it does not expand or contract, blister, flake, or crack, and it is asserted that it can be made absolutely fire-proof. It is said that its cost is exceedingly low.

**Church Service by Telephone.**—As mentioned in our last issue, Christ Church, Birmingham, was to be connected by telephone. The experiment proved to be a distinct success, the service being well heard in London, Manchester, Derby, and other places. A local paper says when the morning service began there was what appeared to be an unseemly clamour to hear the service, and the opening prayer was interrupted on the wires by irreverent cries of "Hallo there." "Are you there." "No, I don't want the church."

**Laying a Telephone Cable.**—The *New York Electrical Engineer* of September 17th, contains an article on the laying of a telephone cable across the Hudson River. It appears that the Western Union Telegraph Company maintains an especially equipped cable steamer for the purpose of laying and repairing the numerous cables crossing the North River. This boat is called the *Western Union*, has much the appearance of a river tug, and is about 50 feet in length by 14 feet beam, and is provided with twin propellers. She has been in commission from January last, and was built to replace the old *Orton*, a vessel which had a long career of usefulness. On the main deck forward of the pilot house is the cable drum, set vertically, the lower side bearing on a number of small rollers fixed to the deck. Round the edge of the lower side of the drum is a brake strap to regulate the speed. The wheel for operating the brake, and a sliding rod by which the valve of the drum engine is opened or closed are placed on the bridge forward of the pilot house. A small iron pulley is attached to the end of a boom which can be swung out so that the pulley hangs clear of the vessel's side by about 8 or 10 feet. This pulley serves as a paying out or picking up sheave. A small steam winch forward of the drum completes the outfit. This arrangement would appear to serve very well for paying out, but for picking up we should imagine it to be a rather awkward method. The cable referred to was made for the Metropolitan Telephone Company, it contains 18 conductors and is of the Kerite type; the length laid was about one mile, and the weight nearly 20 tons.

**Creeping on Cells.**—M. Girard has suggested a simple process for preventing the creeping of salts, which weakens and destroys a cell. The idea is to apply with a brush a light coating of vaseline over the surfaces which require protection. Vaseline is unchangeable in air, is easily applied, and resists the action of a great number of chemical agents. An objection, we think, to the employment of this material lies in its stickiness—dust and all kinds of dirt being liable to adhere. A very ready method is the employment of melted wax; it has the advantage of presenting a smooth and hard surface.

**Telephony in Italy.**—Acting Consul F. T. Turner, of Naples, states that the number of subscribers to the telephone in that locality has not changed during the past two years, new subscribers having taken the place of those retiring. He believes it probable that the public are waiting before joining, in the expectancy that the Government will acquire the telephone service.

**Electric Bath Chair.**—The Vaughan-Sherrin Electrical Engineering Company, to which reference is made in another column, gave another demonstration this week at their works of the applicability of primary battery power to the propulsion of Bath chairs. A strong chair, weighing about 2 cwt., fitted with a battery at the back of the seat, went through some adjacent streets at a rate of about 5 miles an hour, and passed over a canal bridge with very little reduction of speed. As it is calculated that the cost of maintenance of the battery does not exceed 2d. per hour, and as no renewal would be required during an ordinary day's use, the application of electric propulsion to the Bath chair may prove both an improvement and an economy, if the claims put forward can be sustained.

**Treating Sewage by Electricity.**—In answer to the questions of a correspondent, we beg to refer him to the number of the *ELECTRICAL REVIEW* for October 11th, 1889.

**Electric Bells for Jamaica.**—Messrs. Cox & Co. have just completed a large installation of electric bells for the Constant Spring Hotel, Jamaica, including two of their improved electric reversing annunciators of 75 numbers each.

**Gutta-percha.**—At the meeting of the Paris Academy of Sciences, on September 15th, M. Serullas read a paper on the *Isonandra Gutta*. The author gives an account of this plant, both as to its discovery and as to the growth of certain varieties. Some interesting information with regard to the employment of gutta-percha for industrial and commercial purposes is also given.

**Personal.**—Mr. A. Grundy has retired from the firm of Baily and Grundy, of Paddington and Cambridge, and joined the staff of the Gülcher Electric Light and Power Company, Limited.

**Newcastle-upon-Tyne Electric Supply Company.**—The offices of this company are removed to the works at Pandon Dene, Newcastle.

**Telephonic.**—An important test of the capabilities of the Berthon telephone to work on telegraph wires is about to be made on the railway telegraph wires between Perth and Inverness.

**Electric Tramway.**—Bailies Paton and M'Farlane, of Glasgow, accompanied by Mr. Rankine, engineer, are in Birmingham gathering information about the electric tramways.

**Woodhouse and Rawson v. Appleton, Burbey, and Williamson.**—This cricket match was played at Brentwood, Essex, on Saturday last, and, after an enjoyable game, ended in an easy win for the former by nearly 300 runs.

**A Telegraph Superintendent Killed.**—William York, an *employé* of the Midland Railway, in charge of the telegraph extensions, met with a fearful death last week at Thwaites, a village near Bradford. He was engaged supervising the workmen under his control, and, not noticing the advance of the 10.30 express from Leeds, stepped on the line in front of it. His body was cut into two pieces in the sight of his workmen.

**New Electrical Journal.**—To-morrow there is to be started a penny weekly paper, entitled, *Electricity*. The editor is Dr. Julius Maier, and the publishers Messrs. Swan, Sonnenchein & Co.

**Seasonable Caution.**—*Electrical Plant* wonders when young and aspiring electricians, at the beginning or early period of their experience as masters, will learn that the manufacture of dynamos is *not* the certain road to fortune. Reckoning up the present number of dynamo manufacturers, our contemporary concludes that the capacity for supply greatly exceeds the demand, and advises young electricians to eschew any attempts to add to the number already in the market.

**"Martin" Wires.**—The Telegraph Administrations of Greece, Sweden and Switzerland have, following the lead of France, adopted the bi-metallic "Martin" wires for their telegraph and telephone systems.

**Electricity in Australia.**—The Australian papers by the last mail say that it is intended to place the electric light in the New South Wales Parliament. Previously gas has been used, but numerous has been the complaints against the heat, so it is resolved to adopt electricity. An interesting exhibition was given in the central station of the electric light company in Melbourne some nights ago. At the invitation of the engineer, prominent citizens had gathered to witness, as far as Australia is concerned, a new departure made by electricity. It was nothing more than making a cook-shop of the station. By a method which was not communicated, beef steaks were well cooked, toast was made, water boiled, and most of the culinary arts received attention.

**Buller, Jobson & Co., Limited.**—This company has acquired a site for extensive new works at Cheston Road, Birmingham. The company is to be reconstructed with extended powers and the capital has been increased. The proprietary remains the same, but the name is to be changed to Bullers, Limited.

**The Madrid School of Mines.**—It has been determined by the Official Inspectors of the Madrid School of Mines to devote a class for the instruction of pupils in electricity as applied to mining and metallurgy. There seems, however, to be some difficulty as to the appointment of a thoroughly qualified professor in this particular branch of electro-technics.

**Reduction in the Price of Tubes and Fittings.**—Joseph Aird, Tube Works, Great Bridge, Staffordshire, and 46, Queen Victoria Street, E.C., gives notice that he has increased his discounts 5 per cent. gross upon gas, steam, galvanised, and water tubes and fittings.

#### NEW COMPANIES REGISTERED.

**Elmore's Austro-Hungarian Patent Copper Depositing Company, Limited.**—Capital £200,000, in £2 shares. Objects: To carry out an agreement entered into with the Elmore Foreign and Colonial Depositing Company, Limited, and Woodhouse and Rawson United, Limited. To carry on in Austria, Hungary, and elsewhere the business of manufacturers of and dealers in copper and other metals, and all metallic alloys or compounds of the same. To supply electricity in all branches, and to carry on the business of electricians, electrical contractors, electrical and mechanical engineers. Signatories (with 1 share each): G. Worrall, 29, Percy Road, Forest Gate; J. Mumford, 50, Trinity Square, Borough; A. M. G. Carter, 40, Danning Road, Hampstead; B. F. Howard, Beckenham; H. Villars, 6, Penshurst Road, N.E.; A. W. Taylor, 53, Bloemfontein Avenue, Shepherd's Bush; and E. W. Clayton, Southfields, S.W. The signatories appoint the first directors, any shareholder being eligible; remuneration £200 per annum each, with an additional £200 for the chairman and £100 for the vice-chairman, also 2½ per cent. commission upon the net profits made from manufacturing and upon the revenue accruing from licensing or sub-licensing the company's patents; and 1 per cent. upon the net profits made from sales of patents, licenses, or businesses. Registered 26th ult. by Ashurst, Morris and Co., 6, Old Jewry, E.C.

**Unsworth and Richmond, Limited.**—Capital £20,000, in £10 shares. Objects: To take over the business of manufacturer of gas cooking and heating appliances carried on by Wm. Unsworth at Warrington. To carry on business as gas, electrical, and general engineers. Signatories (with 1 share each): \*Wm. Mortimer, \*Wm. Unsworth, \*L. Voisey, W. D. Jeans, all of Warrington; E. Richmond, Leicester; Wm. Atkins, Matlock; \*E. W. T. Richmond, Southport. The signatories denoted by an asterisk are the first directors; qualification, 50 shares; the company in general meeting will appoint remuneration. Registered 26th ult. by Field, Roscoe & Co., 36, Lincoln's Inn Fields.

#### OFFICIAL RETURNS OF ELECTRICAL COMPANIES.

**Buenos Ayres Electric Light Company, Limited.**—The annual return of this company, made up to the 14th June, 1889, was filed on the 20th ult. The nominal capital is £100,000, divided into 9,986 shares of £10 each and 70 founders' shares of £2 each. At the date of the return the founders' shares had been allotted, but no call had been made in respect thereof.

The return for the present year is made up to the 14th June, 1890, and was filed on 20th September. The only shares recorded as taken up are the 70 founders'

shares, upon which no amount has been called or paid, so that the company continues without an actual paid up capital.

**MacMahon's Electric Automatic Registering Company, Limited.**—At a meeting of this company, held on the 18th of August, an account was given as to the way in which the winding up of the company has been conducted, and its property disposed of. The notification of such meeting was filed on the 23rd ult.

**Exeter Electric Light Company, Limited.**—An agreement of 9th September, filed 27th September, between this company and the Brush Electrical Engineering Company, Limited, cites, that the latter company had agreed to sell and deliver to the Exeter Company, certain machinery and articles, and would accept payment of one-third of the price by an allotment of shares to the amount of one-third of the price. in the ordinary share capital of this company. Machinery and articles to the value of £2,160 have been supplied, and, in accordance with such arrangement, 72 fully paid shares of £10 each will form part of the purchase consideration.

**Provincial Electric Light and Power Supply Limited.**—The registered office of this company is at Westminster Chambers, 5, Victoria Street, Westminster.

**Stamford Hill, Tottenham and Edmonton Electric Light and Power Supply, Limited.**—The registered office of this company is at Westminster Chambers, 5, Victoria Street, S.W.

**Camberwell and Islington Electric Light and Power Supply, Limited.**—The registered office of this company is situate at Westminster Chambers, 5, Victoria Street, S.W.

**Devonshire Electric Light and Power Supply, Limited.**—The registered office of this company is situate at Westminster Chambers, 5, Victoria Street, S.W.

**Barry and Cardiff Electric Light and Power Supply, Limited.**—The registered office of this company is situate at Westminster Chambers, 5, Victoria Street, Westminster.

**East Coast Electric Light and Power Supply, Limited.**—The registered office is at Westminster Chambers, 5, Victoria Street, Westminster.

**Kidderminster Electric Light and Power Supply, Limited.**—The registered office is situate at Westminster Chambers, 5, Victoria Street, Westminster.

**Maxim-Weston Electric Company, Limited (in Liquidation).**—The registered office of this company is now situate at the Works, Boleyn Road, Kingsland Green, N.E.

## CITY NOTES, REPORTS, MEETINGS, &c.

### The Direct Spanish Telegraph Company, Limited.

SIR JAMES ANDERSON presided at the half-yearly meeting of shareholders held at Winchester House on Tuesday last, and, in presenting the directors' report (printed in our last issue), and accounts for the half year, said: The shareholders would remember that at the last meeting he spoke of the approaching Telegraphic Conference as having some new terrors for the company, especially as regards its tariff of 4½d. a word. The odd half-penny had in fact been taken away, and but for the good offices of the Post Office delegate, and the Spanish delegates, the company might have fared even worse. It seemed a small matter to cry over, but that half-penny with other small adjustments, represented a sum of £3,500 a year. It required some confidence in order to feel sanguine that it would be recouped by an increase of traffic, still he thought that to a large extent it would be recouped. During the last three years the company's traffic had been steadily increasing; the commercial interests of Spain seemed to have taken a very promising start in the company's interests. He spoke last year of the use of code language and the effect it had in reducing the tariffs of cable companies. Codes were so scientifically arranged that whole circulars could be telegraphed in one or two words. He believed he spoke within bounds when he said

that the average of every word of code language was nearly ten ordinary words. Indeed, he had known some to express 24 and 25 words of plain language. That seemed at one time to threaten a reduction in the company's revenue, and in the length of messages at the rate of one word per message per annum. This year, however, he was happy to tell them there had been a slight increase in the length of messages. He was sorry to say that the company's managers would not let him attribute it to causes connected with the ordinary conditions of commerce. They attributed it to other causes which he would not dwell upon. For the last two years the company's earnings had been at about the same level, and if the traffic continued to increase, and code language remained unchanged, it would get along fairly well. Last year the company made a round £1,500 more money and carried one hundred and sixty thousand more words at a cost of £300 odd. This year it had carried two hundred thousand and odd words more, and had increased its revenue by £2,000 odd at a smaller outlay of £300 odd. Apparently it was on the right track. All its cables were in good order. On the other hand, they had to face the necessity for duplexing their cable at a cost of nearly £800. For that and some other reasons he advised them not to make use of the money. With a 6 per cent. dividend and an increase in the commercial revenue, he thought the directors would not act prudently if they failed to keep before them the fact that the company had a debenture debt of £62,000, carrying interest at 6 per cent. It was not a sound position to be in, and therefore they ought to allow their directors to devote any surplus to wiping off this debenture debt and duplexing their cable. They could then look forward to 1894, when the debentures fell due; and they might possibly be in a position to lay down an additional cable if the traffic continued to increase. The £20,000 they had in reserve would not go very far towards the cost of a new cable. The directors were very anxious to have a sum in hand for contingencies without trenching upon the reserve fund. If in 1894 these conditions—a sound property and an increasing traffic, with a 6 per cent. dividend—continued, he anticipated no difficulty in finding money amongst themselves to pay off their debenture debt. By that time their reserve would be £40,000 or with the cash in hand £50,000; and they would be able to say with confidence that the Direct Spanish was one of the soundest telegraph investments in London.

Mr. Etlinger seconded the motion which was carried unanimously.

The Chairman also moved, seconded by Mr. Etlinger, the declaration of a dividend of 10 per cent. per annum, less income tax on the preference shares, and of 6 per cent. per annum on the ordinary shares, free of income tax, both for the half-year ending 30th June, 1890. The motion was carried unanimously.

An extraordinary meeting was then held and the following special resolution was unanimously passed:—"That Article 71 of the Articles of Association of the company be and is hereby repealed and instead thereof the following be a regulation of the company."

"The directors shall receive as remuneration for their trouble in the execution of their office the sum of £600 per annum, or such other sum as the company in general meeting may from time to time determine, and such remuneration shall be apportioned by the directors among themselves in such manner as they shall from time to time think fit."

The proceedings then closed with a vote of thanks to the Chairman and directors.

**Elmore's Austro-Hungarian Patent Copper Depositing Company, Limited.**—The capital is £200,000, of which 75,000 shares of £2 each are now offered for subscription at a premium of 10s. per share, and 25,000 are accepted in part payment of the purchase money. This company has been formed to acquire the patents for the Empire of Austria-Hungary relating to the discovery made by Messrs. Francis Edward Elmore and Alexander Stanley Elmore, for manufacturing copper articles direct from rough copper bars, with right to the Messrs. Elmore to use the said patents for certain special applications. The invention, it is claimed, does away with the processes of melting, rolling, forging, drawing &c., and the present costly and laborious methods of manufacturing.

**Anglo-American Telegraph Company, Limited.**—The directors declare an interim dividend for the quarter ending 30th September, 1890, of 15s. per cent. on the ordinary stock, and £1 10s. per cent. on the preferred stock, less income tax, payable on the 1st November, to the stockholders registered on the books of the company on the 30th September, 1890.

**Eastern Telegraph Company, Limited.**—The directors announce the usual 2s. 6d. interim dividend.

**Submarine Cables Trust.**—The payment on the 15th inst. of the coupons due in April last is notified.

### TRAFFIC RECEIPTS.

The Brazilian Submarine Telegraph Company, Limited. The traffic receipts for the week ending September 26th, were £4,970.

The Western and Brazilian Telegraph Company, Limited. The receipts for the week ending September 26th, after deducting the fifth of the gross receipts payable to the London Platino-Brazilian Telegraph Company, Limited, were £3,899.

THE ELECTRO-MAGNET.\*

By Prof. SILVANUS P. THOMPSON, D.Sc., B.A., M.I.E.E.

(Continued from page 376.)

(C) *Divided Bar Method.*—This method, due to Dr. Hopkinson,† is illustrated by fig. 17.  
The apparatus consists of a block of annealed wrought iron about 18 inches long, 6½ wide, 2 deep, out of the middle of which is cut out a rectangular space to receive the magnetising coils.

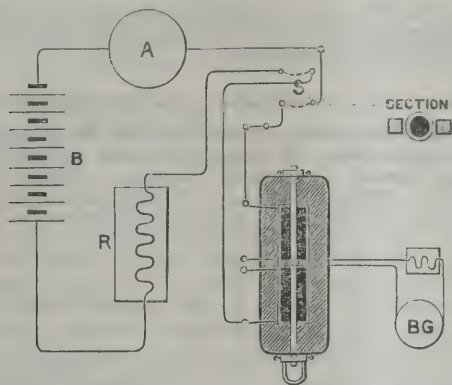

FIG. 17.—HOPKINSON'S DIVIDED BAR METHOD OF MEASURING MAGNETIC PERMEABILITY.

The test samples of iron consist of two rods, each 12·65 millimetres in diameter, turned carefully true, and slide in through holes bored in the ends of the iron blocks. These two rods meet in the middle, their ends being faced true so as to make a good contact. One of them is secured firmly, and the other has a handle fixed to it, by means of which it can be withdrawn. The two large magnetising coils do not meet, a space being left between them. Into this space is introduced the little exploring coil, wound upon an ivory bobbin, through the eye of which passes the end of the movable rod. The exploring coil is connected to the ballistic galvanometer, BG, and is attached to an India-rubber spring (not shown in the fig.), which, when the rod is suddenly pulled back, causes it to leap entirely out of the magnetic field. The exploring coil had 350 turns of fine wire; the two magnetising coils had 2,008 effective turns. The magnetising current, generated by a battery, B, of eight Grove cells, was regulated by a variable liquid resistance, R, and by a shunt resistance. A reversing switch and an amperemeter, A, were included in the magnetising circuit. By means of this apparatus the sample rods to be experimented upon could be submitted to any magnetising forces, small or large, and the actual magnetic condition could be examined at any time by breaking the circuit and simultaneously withdrawing the movable rod. This apparatus, therefore, permitted the observation separately of a series of increasing (or decreasing) magnetisations without any intermediate reversals of the entire current. Thirty-five samples of various irons of known chemical composition were examined by Hopkinson, the two most important [for present purposes] being an annealed wrought iron

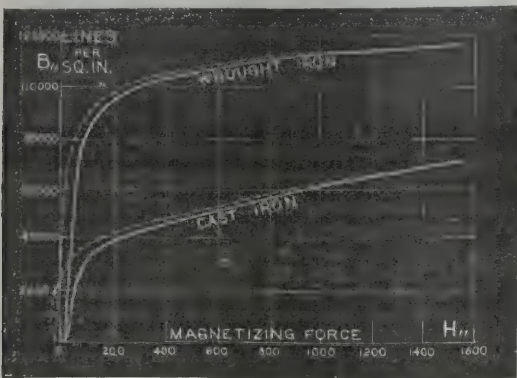

FIG. 18.—CURVES OF MAGNETISATION OF IRON.

and a grey cast iron, such as are used by Messrs. Mather and Platt in the construction of dynamo machines. Hopkinson embodied his results in curves, from which it is possible to construct, for purposes of reference, numerical tables of sufficient accuracy to serve for future calculations. The curves of these two samples of iron are reproduced in fig. 18, but with one simple modification.

\* Cantor Lecture. Delivered before the Society of Arts, January 20th, 1890.  
† "Phil. Trans.," 1885, p. 564.

British engineers who unfortunately are condemned by local circumstances to use inch measures instead of the international metric system, prefer to have the magnetic facts also stated in terms of square inch units instead of square centimetre units. This change has been made in fig. 18, and the symbols  $B_{in}$  and  $H_{in}$  are chosen to indicate the numbers of magnetic lines to the square inch in iron and in air respectively. The permeability, or multiplying power of the iron is the same, of course, in either measure. In Table II. are given the corresponding data in square inch measure; and in Table III. the data in square centimetre measure for the same specimens of iron.

20,000	30	666	—	—	—

It will be noted that Hopkinson's curves are double, there being one curve for the ascending magnetisations, and a separate one, a little above the former, for descending magnetisations. This is a point of a little importance in designing electro-magnets. Iron, and particularly hard sorts of iron, and steel, after having been subjected to a high degree of magnetising force, are subsequently to a lesser magnetising force found to retain a higher degree of magnetisation than if the lower magnetising force had been simply applied. For example, reference to fig. 18 shows that the wrought iron, where subjected to a magnetising force gradually rising from zero to  $H_{in} = 200$ , exhibits a magnetisation of  $B_{in} = 95,000$ ; but after  $H_{in}$  has been carried up to over 1,000, and then reduced again to 200,  $B_{in}$  does not come down again to 95,000, but only to 93,000. Any sample of iron which showed great retentive qualities, or in which the descending curve differs widely from the ascending curve, would be unsuitable for constructing electro-magnets, for it is important that there should be as little residual magnetism as possible in the cores. It will be noted that the curves for cast iron show more of this residual effect than do those for wrought iron. The numerical data in Tables II. and III. are means between the ascending and descending values.

As an example of the use of the tables, we may take the following:—How strong must the magnetising force be in order to produce in wrought iron a magnetisation of 110,000 lines to the square inch? Reference to Table II., or to fig. 18, shows that a magnetising field of 664 will be required, and that at this stage of the magnetisation the permeability of the iron is only 166. As there are 6·45 square centimetres to the square inch, 110,000 lines to the square inch correspond very nearly to 17,000 lines to the square centimetre; and  $H_{in} = 664$  corresponds very nearly to  $H = 100$ .

TRACTION METHODS.

Another group of methods of measuring permeability is based upon the law of magnetic traction. Of these there are several varieties.

(D) *Divided Ring Method.*—Mr. Shelford Bidwell has kindly lent me the apparatus with which he carried out this method. It consists of a ring of very soft charcoal iron rod 6·4 millimetres in thickness, the external diameter being 8 centimetres, sawn into two half rings, and then each half carefully wound over with an

exciting coil of insulated copper wire of 1,929 convolutions in total. The two halves fit neatly together; and in this position it constitutes practically a continuous ring. When an exciting current is passed round the coils both halves become magnetised and attract one another. The force required to pull them asunder is then measured. According to the law of traction, which will occupy us in the second lecture, the tractive force (over a given area of contact) is proportional to the square of the number of magnetic lines that pass from one surface to the other through the contact joint. Hence the force of traction may be used to determine  $B$ ; and on calculating  $H$  as before, we can determine the permeability. The following Table IV. gives a summary of Mr. Bidwell's results.

(E) *Divided Rod Method.*—In this method, also used by Mr. Bidwell, an iron rod hooked at both ends was divided across the middle, and placed within a vertical surrounding magnetising coil. One hook was hung up to an overhead support; to the lower hook was hung a scale-pan. Currents of gradually-increasing strength were sent around the magnetising coil from a battery of cells, and note was taken of the greatest weight which

TABLE IV.—(Square centimetre measure.)

Soft charcoal iron.		
B	$\mu$	H
7,390	1899.1	3.9
11,550	1121.4	10.3
15,460	386.4	40
17,330	150.7	115
18,470	88.8	208
19,330	45.3	427
19,820	33.9	585

could in each case be placed in the scale-pan without tearing asunder the ends of the rods.

(F) *Permeameter Method.*—This is a method which I have myself devised for the purpose of testing specimens of iron. It is essentially a workshop method, as distinguished from a laboratory method. It requires no ballistic galvanometer, and the iron does not need to be forged into a ring or wound with a coil. For

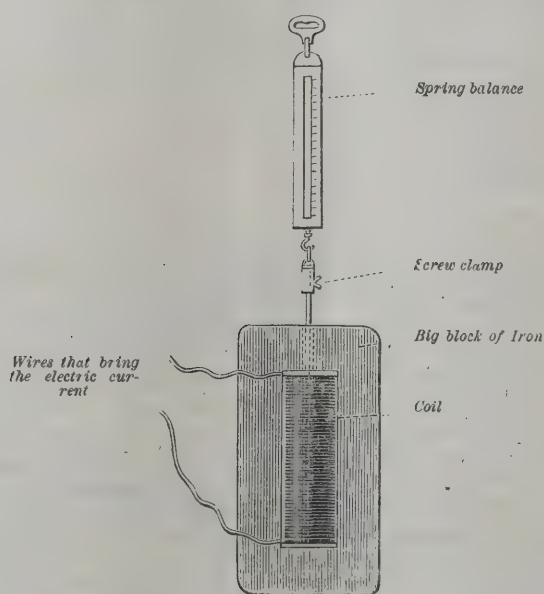

FIG. 19.—THE PERMEAMETER.

carrying it out a simple instrument is needed, which I venture to denominate as a *permeameter*. Outwardly, it has a general resemblance to Dr. Hopkinson's apparatus, and consists, as you see (fig. 19), of a rectangular piece of soft wrought-iron, slotted out to receive a magnetising coil, down the axis of which passes a brass tube. The block is 12 inches long, 6½ inches wide, and 3 inches in thickness. At one end the block is bored to receive the sample of iron that is to be tested. This consists simply of a thin rod about a foot long, one end of which must be carefully surfaced up. When it is placed inside the magnetising coil, and the exciting current is turned on, the rod sticks tightly at its lower end to the surface of the iron block; and the force required to detach it (or, rather, the square root of that force) is a measure of the permeation of the magnetic lines through its end-face. In the first permeameter which I constructed the magnetising coil is 13.64 centimetres in length, and has 271 turns of wire. One ampère of exciting current consequently produces a magnetising force of  $H = 34$ . The wire is thick enough to carry 30 amperes, so that it is easy to reach a magnetising force of 1,000. The current I now turn on is 25 amperes. The two rods here are of "charcoal iron"

and "best iron" respectively; they are of quarter-inch square stuff. Here is a spring balance graduated carefully and provided with an automatic catch so that its index stops at the highest reading. The tractive force of the charcoal iron is about 12½ lbs., while that of the "best" iron is only 7½ lbs.  $B$  is about 19,000 in the charcoal iron, and  $H$  being 850,  $\mu$  is about 22.3. The law of traction which I use in calculating  $B$  will occupy us much in the next lecture, but meantime I content myself in stating it here for use with the permeameter. The formula for calculating  $B$  when the core is thus detached by a pull of  $P$  pounds, the area of contact being a square inches, is as follows:—

$$B = 1,317 \times \sqrt{P \div A + H}.$$

I may add that the instrument, in its final form, is manufactured from my designs by Messrs Nalder Bros., the well-known makers of so many electrical instruments.

## CURVES OF MAGNETISATION AND PERMEABILITY.

In reviewing the results obtained, it will be noted that the curves of magnetisation all possess the same general features, all tending toward a practical maximum, which, however, is different for different materials. Joule expressed the opinion that "no force of current could give an attraction equal to 200 lbs. per square inch," the greatest he actually attained being only 175 lbs. per square inch. Rowland was of opinion that the limit was about 177 lbs. per square inch for an ordinary good quality of iron, even with infinitely great exciting power. This would correspond roughly to a limiting value of  $B$  of about 17,500 lines to the square centimetre. This value has, however, been often surpassed. Bidwell obtained 19,820, or possibly a trifle more, as in Bidwell's calculation the value of  $H$  has been needlessly discounted. Hopkinson gives 18,250 for wrought iron, and 19,840 for mild Withworth steel. Kapp gives 16,740 for wrought iron, 20,460 for charcoal iron in sheet, and 23,250 for charcoal iron in wire. Bosanquet found the highest value in the middle bit of a long bar to run up in one specimen to 21,428, in another to 29,388, in a third to 27,688. Ewing, working with extraordinary magnetic power, forced up the value of  $B$  in Lowmoor iron to 31,560 (when  $\mu$  came down to 3), and subsequently to 45,350. This last figure corresponds to a traction exceeding 1,000 lbs. to the square inch.

Cast iron falls far below these figures. Hopkinson, using a magnetising force of 240, found the values of  $B$  to be 10,783 in grey cast iron, 12,408 in malleable cast iron, and 10,546 in mottled cast iron. Ewing, with a magnetising force nearly fifty times as great, forced up the value of  $B$  in cast iron to 31,760. Mitis metal, which is a sort of cast wrought iron, being a wrought iron rendered fluid by addition of a small percentage of aluminium, is, as I have found, more magnetisable than cast iron, and not far inferior to wrought iron. It should form an excellent material for the cores of electro-magnets for many purposes where a cheap manufacture is wanted.

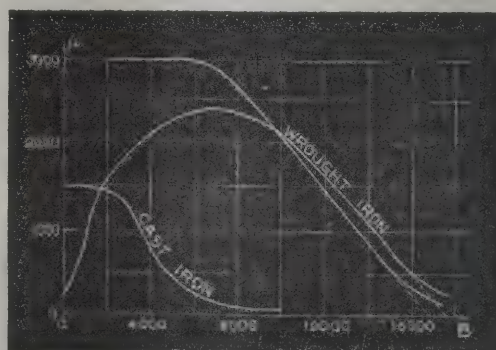

FIG. 20.—CURVES OF PERMEABILITY.

A very useful alternative mode of studying the results obtained by experiment is to construct curves, such as those of fig. 20, in which the values of the permeability are plotted out vertically in correspondence with the values of  $B$  plotted horizontally. It will be noticed that in the case of Hopkinson's specimen of annealed wrought iron, between the points where  $B = 7,000$  and  $B = 16,000$ , the mean values of  $\mu$  lie almost on a straight line, and might be approximately calculated from the equation:—

$$\mu = (17,000 - B) \div 3.5.$$

## THE LAW OF THE ELECTRO-MAGNET.

Many attempts have been made, by Müller, Lamont, Frölich, and others to discover a simple algebraic formula whereby to express the relation between the magnetising force and the magnetism produced in the electro-magnet. According to Müller, these are related to one another in the same proportions as the natural tangent is related to the arc which it subtends. The formulæ of Lamont and Frölich, which are more nearly in keeping with the facts, are based upon the assumption of a relation between the permeability and the degree of magnetisation present. Suppose we assume the approximation stated above, that the permeability

is proportional to the difference between  $B$  and some higher limiting value (17,000 for wrought iron, 7,000 for cast iron). If this higher value is called  $\beta$  we may write

$$\mu = \frac{\beta - B}{a},$$

where  $a$  is a constant that varies with the quality of the iron or steel

Now  $B = \mu H$ ;

giving by substitution and an easy transformation—

$$B = \beta \frac{H}{a + H},$$

which is one form of Frölich's well-known formula. The constant,  $a$ , stands for the "diacritical" value of the magnetising force, or that value which will bring up  $B$  to half the assumed limiting or "satural" value.

All such formulæ, however convenient, are insufficient, inasmuch as they fail to take into account the properties of the entire magnetic circuit.

(To be continued.)

## EDINBURGH EXHIBITION.

(Continued from page 205.)

No. 29.—Messrs. Laurence, Scott & Co., Limited, of Norwich, show on the stand of their agents for Scotland (Messrs. Norman & Son, Limited, Glasgow) among other things, one of their "D 7" dynamos driven by a long stroke engine by Messrs. Ransomes, Sims & Jefferies, of Ipswich. In this dynamo the magnets are of the "Kapp" type, made of specially soft cast iron, and the machine has three very long bearings. The magnets are very massive and the whole thing makes a perfectly rigid combination. The armature is built up on the system which Messrs. Laurence, Scott & Co., Limited, have used successfully for several years; it is a drum armature, and the plates are stamped with hexagonal holes placed, together with the insulating material between them, on a temporary hexagon mandril which, being removed, the hexagon spindle is driven into them very tightly with strips of vulcanised fibre to insulate the plates from the spindle. A section of this type of armature is shown with magnets of the "Manchester" type, from which it can be seen that the conductor is wound in deep and narrow slots milled into the plates.

The output of the machine is 110 volts, 140 ampères, at 1,160 revolutions per minute. There are 70 sections in the commutator, and 70 turns of conductor on the armature, so that there is only one turn of conductor per section. The armature core is nearly square in longitudinal section, being  $7\frac{1}{4}$  inches in diameter and  $7\frac{1}{2}$  inches long. The conductor on the armature consists of two parallels of  $\frac{1}{12}$  inch round wire braided, the resistance of the armature when hot, being .024 ohms. The shunt winding consists of 147 lbs. No. 17 wire, and the series of 73 lbs. No. 6 wire, in four parallels, there being 8,560 ampère turns in the shunt and 5,520 in the series, total number of ampère turns, 14,080. The watts lost in the field magnets are 408; the total electrical efficiency of the machine, 94.6 per cent. The total weight of conductor on the armature, including commutator connections, is only 21 lbs., being 733 watts per pound of copper.

There is also shown a ship-lighting plant by the same firm. The armature of the dynamo is of the same type as that of the belt-driven one described above. This construction of armature is specially applicable to these slow speed direct-driven machines, in which the strains between the shaft and the armature conductor are so much greater and more trying than in an ordinary belt-driven machine. The output of the dynamo is 60 volts, 75 ampères, at the slow speed of 260 revolutions per minute. Messrs. Laurence, Scott & Co. always test these ship lighters before leaving their works for 6 hours at "load and-a-half," and for 12 hours at full load. The engine is by

Messrs. Sabberton Bros., of Norwich. The crank is of forged steel, slotted and fitted with balance weights; the connecting rod is also of forged steel. All the bearings and wearing surfaces are very large and fitted with suitable lubricating arrangements to enable it to run continuously at a high speed. The cylinders are 6 inches diameter and 6 inches stroke, and the engine will run well up to 400 revolutions per minute.

## TELEPHONE CABLES.

UP to the year 1889, nearly every telephone company in the United States employed a different type of cable. These types differed not only in construction, number of conductors, methods of insulating and protecting, conduit systems, &c., but they also showed the widest variations in their insulation resistances. To remedy this inconvenience and to determine upon some uniform type of cable and a standard resistance, a conference was assembled in May 1889, in New York, at the invitation of the American Telephone and Telegraph Company (the Long Distance Telephone Company), an association which has generally taken the lead in all technical questions pertaining to telephony. The decisions arrived at by the conference were as follows:—

The cables should be composed of 50 double wires. The wires to be 1.025 mm. diameter of copper, the conductivity to be not less than 98 per cent. pure copper. Each wire should be covered with a double coating of braided cotton. The wires should be laid up in layers; in cables of 50 double wires the centre layer to be of three double wires, the next of 9, the next of 16 and the outside layer of 23 double wires. Each layer to be laid up in an opposite direction to the preceding one.

The cable thus formed should be placed in a pipe made of 97 per cent. lead and 3 per cent. tin. This mixture of tin with lead was adopted in order to preserve the latter from the injurious action of creosote. The vacant space in the pipe should then be filled with some insulating compound. The inductive capacity of each wire, after laying down, should not exceed 0.18 microfarads, and the insulation resistance should not be less than 100 megohms per mile. The pipes should be protected by a coating of asphalt, with an external covering of two layers of fibrous material, impregnated with some preservative compound, and laid on in opposite directions.

In the Patterson type of what was called the "conference cable," the insulating compound run into the pipe was paraffine impregnated with carbolic acid, and the external covering was of cotton tape. In the Faraday type of the same cable, pyroligneous oil was used as an insulator, and the cable was covered externally with jute impregnated with asphalt.

The price of the "conference cable" of 100 wires, was 70 cents per foot in New York, and the laying in conduits, in the same town, cost from 5 to  $7\frac{1}{2}$  cents the foot-run.

At the time the conference was assembled, experiments were being carried out by the Norwich Insulated Wire Company, with Manilla paper as a covering for the wires instead of cotton. It was claimed that a diminution of 30 per cent. in the inductive capacity was obtained by the employment of the paper, and that it was of a far less hygroscopic nature than cotton. The price was stated to be about the same as that of the "conference cable." The conference came to the conclusion that these experiments deserved every attention, since the question of inductive capacity formed so important an element in the working of telephone cables

## THE ELECTRIC LIGHTING OF TEPLITZ.

[FROM A CORRESPONDENT.]

As I recently informed you, the authorities of the Bohemian watering place have resolved not to renew the gas agreement which expires in August next, but to erect large municipal electric works. The official report of the committee for considering this project, contains on the one hand many interesting data on the comparative cost of electric lighting and of gas, and on the other hand communications and revelations which throw a very peculiar light upon the endeavours of gas companies to maintain their former position under all circumstances, and without any regard to the means employed.

I will, in the first place, give the proposals of the "Department of Works," which explain the estimates of comparative cost, in consequence of which the erection of the municipal electrical works was resolved on. They are as follows:—

According to the present and the probable circumstances of the town, the following data may be laid down:—

The renewal of the agreement for carrying out the lighting of the public streets and places with coal gas would in round numbers come to about 11,000 florins yearly. The lighting of the municipal buildings formerly named\* would require annually 1,950 florins, and private consumers would have to pay for the hourly service of a gas flame at 12 normal candles 2.88 kreuzers.

If the present public lighting is increased by 60 Wenham lamps, the town would have to pay, in addition to the above-named 11,000 florins, and besides the first cost of procuring and installing the lamps (5,175 florins), 2,500 florins annually.

If the public lighting of the town were carried out with the electric light according to the proposal of the Teplitz-Schönan Gas Company (July 9th, 1890), *i.e.*, with 484 glow lamps at 16 normal candles, and with four arc lamps at 10 ampères, the cost would run up to 18,594 florins 30 kreuzers. The light would then be stronger than it is at present by  $33\frac{1}{3}$ rd per cent. Private consumers, according as their consumption falls below 4,500 glow lights, above 4,500 or above 7,000 glow lights, would have to pay for the burning-hour of a 16-candle glow lamp, respectively,  $3\frac{1}{4}$ ,  $2\frac{1}{2}$  or 2 kreuzers, besides a fundamental tax of 5 florins for each glow lamp.

To the cost of the electric lighting of the municipal buildings in certain streets would be also added the same tax of 5 florins per glow lamp. The water for the central station would (within certain limits) have to be furnished gratuitously by the municipality.

If a combined lighting were introduced according to the offer of the gas company, under date July 29th, 1890, *i.e.*, 30 arc lamps at 10 ampères, in addition to the lights included in the proposals of July 9th, the outlay would amount to 21,500 florins yearly.

If the proposals of the management of Prince Olary's estates (May 15th, 1890), were accepted, *i.e.*, to light up the streets and squares with 16-candle lamps, equal in number (484) to the present 12-candle gas flames, or an increase of the light by one-third the yearly expenditure, would reach 19,078 florins 30 kreuzers.

Private consumers would then have to pay for the burning hour of a 16 normal candle glow lamp,  $3\frac{1}{2}$ ,  $2\frac{1}{2}$ , or 2 kreuzers in addition to the fundamental tax of 6 kreuzers per glow light.

If, lastly, the municipality erects an electric central station for 5,000 glow lamps at 16 normal candles, and keeps this installation in its own hands, the electric lighting of the public streets and places  $5\frac{1}{2}$  times more powerfully than at present, would come to 12,000 florins yearly, and that of the public buildings and theatres,

with a light increased by  $\frac{1}{3}$ rd, would come to 2,000 florins.

If application is made by private consumers for 3,000 glow lamps, there will be a clear profit of 12,000 florins yearly, or the cost of the public lighting will be compensated.

In addition, the municipality would be in a position to supply the inhabitants of Teplitz with electric current of a 16 normal candle glow lamp for 2 kreuzers per hour burning, *i.e.*, taking the strength of the light into account, for 50 per cent. cheaper than the previous gas light. The very cheap fundamental tax—3 florins per glow lamp, as against 5 and 6 florins of the two proposals—would make little difference. Thus, *e.g.*, a gas flame at 16 normal candles, calculated as burning 1,000 hours yearly, would come to 38 florins 40 kreuzers; if burning 450 hours, to 17 florins 28 kreuzers, whilst a glow light at 16 normal candles, in the first case, would cost only 23 florins, and in the second, only 12 florins, which shows an economy of 15 florins 40 kreuzers in the first case, and of 5 florins 28 kreuzers in the second case.

Considering the economical and financial conditions, and remembering how dangerous it would be for the town under present conditions to bind itself by an agreement extending for tens of years, and how injurious such a renewed agreement would be to the community who desire the cheap supply of a light on a level with the advances of the present day, the Department proposes that.

The representatives of the town should resolve:—

1. The municipality of Teplitz makes use of the right secured to it under Section 6 *f.* of the gas agreement of October 12th, 1860, not further to renew the contract entered into with the Teplitz-Schönan Gas Company.

2 (a). The municipality of Teplitz erects an electric central station of the provisional capacity of 5,000 glow lamps of 16 normal candles (burning simultaneously), for lighting up the public streets and places and the municipal buildings, including the theatre, and for supplying electric current to private consumers.

(b). That a credit of 300,000 florins be granted for this purpose.

(c). That the Finance Committee is authorised to make proper arrangements for procuring this sum.

(d). The construction of this central installation is entrusted to the mayor, in conjunction with the committee of works, just as was the case in the construction of the town waterworks.

3. All the proposals for renewing the gas agreement, or for introducing any other kind of lighting, made by the gas company, or by the inspection of Prince Olary's estates, are declined with thanks.

4. The Mayor is requested to negotiate with the Teplitz-Schönan Gas Company, and to ascertain if, and on what conditions, they are disposed to prolong their agreement for five months, that is, to the end of the year 1891.

The report mentions, further, that the gas company seeks on the one hand to deny the right of the town to break off the agreement, and on the other hand it claims for itself the exclusive right to use the municipal territory for laying down light conductors of whatever kind (therefore including electric light leads).

As regards the latter question, it must be pointed out that in the year 1858 the town made an agreement with the gas company, and conceded to the latter the exclusive right of laying down the mains and branch pipes required for lighting the streets, public and private buildings, in the squares, streets and lanes of the territory of the town of Teplitz.

The sector concerned makes mention simply of *main* and *bye-pipes*, and not expressly of gas pipes. But the object of the entire agreement is simply gas lighting, to which all the mutual rights and duties are referred. In particular the word *pipes* refers formally to gas conductions which are laid as pipes. Still, the gas company now seeks to extend the exclusive right, granted in the year 1858, to electric leads, regardless of the fact that such leads are not pipes, and that it con-

\* Not in the present report.

sequently can raise no claim to them, even in the simple sense of the words.

The former question raised is still more interesting, *i.e.*, that as to the right of setting aside the agreement for public lighting. This question turns upon section 6 of the agreement, which runs as follows:—

"The municipality shall, however, at any time have the option, after the expiry of the first 20 years, to arrange for its own lighting, and on other illuminating material, if it considers that such will be cheaper, and, therefore, entirely to renounce this agreement after the lapse of the first 20 years."

Hence it appears that the town has the right at any time after the lapse of the first 20 years to withdraw from the agreement. The gas company has, indeed, already recognised this right in a proposal handed in on November 30th, 1889, for lighting the streets of Teplitz from August 1st, 1891, to July 31st, 1901. In this document we read:—

"In considering our present proposal, we beg to point out that according to section 6 *f* (quoted above) of the agreement, extending to the year 1911, the municipality is, indeed, entitled from August 1st, 1891, to undertake its own lighting with another illuminating material; but, in this case, it cannot be demanded that the gas company should undertake the gas lighting for the other streets at the previous price of 20 florins yearly per burner."

Nevertheless, the gas company, now threatened with the competition of a municipal electrical works, ventures on the impossible interpretation that the town Teplitz had the right of withdrawing from the agreement *only after the first 20 years*, but has lost this right, as it has not put it in force after the first 20 years. In other words, that it could have enforced this right only at the immeasurable moment of the lapse of the first 20 years.

It may be taken for granted that gas companies cannot carry the day by dint of such ultra-pettifogging constructions. It was certainly superfluous to combat and to refute the pretensions of the Teplitz Gas Company in a pamphlet of 18 pages; but it is instructive to see what we may expect on the part of gas companies, and how cautious town councils should be in drawing up agreements concerning lighting.

## CORRESPONDENCE.

### The Bremen Electric Tramway.

We have read on page 319 of the REVIEW of September 19th, an editorial note to the effect that we have experienced a rebuff on the part of the Bremen Town Council, and that the tramway has worked unsatisfactorily.

Wherever you obtained this information, it is absolutely incorrect, and is exactly what was said by the *Elektro-Technischen Anzeiger*, of Berlin, in their publication of September 4th.

Aside from the letter of correction which we immediately addressed to the Berlin journal, the Bremen Tramway Company, for whom we have made the electrical equipment in question, wrote as follows:—

"To the Editor of the *Elektro-Technischen Anzeiger*,  
"Berlin.

"In No. 71 of your esteemed journal, there is an article as follows:—

"The request of the Thomson-Houston Company to erect an electric railway in Bremen was refused, because the trial plant did not satisfy the conditions during the Exhibition."

"The undersigned Share Company, which has the concession for the line Börse to Bürgerpark (Exhibition), which road was installed by the Thomson-Houston International Electric Company, is directly interested that the shareholders be not led to believe the untrue statements contained in this article, to the

effect that this plant is a failure; further, that the public be not deterred, by mistaken or false statements in this article from using this electric road.

"We therefore request you, on the basis of Sec. 11 of the Press Law, to insert in your esteemed paper the following corrections:—

"1. It cannot be said that the demand of the Thomson-Houston Company was refused, because the Tramway Company has the allowance for electric running at present during the time of the Exhibition, and up to date the Thomson-Houston Company have never asked the municipality in question for permission to continue running this road.

"2. It is further stated in your article:—

"A specially objectionable feature is the unbearable rattling noise, and the strong sparking between wheels and rails."

"The statement as to the unbearable rattling noise, is only an invention of the writer of the article, and the sparking is not stronger than with any electric road when the rails are not free from sand. The sparking is even considered to be minimum by all experts, and this electric road is so much liked by the public that they decidedly prefer the electric cars to the horse cars, notwithstanding the somewhat higher fare.

"The article mentions the whole plant as defective, but, as a matter of fact, during the now nearly three months' operation, not the slightest disturbance has happened which could be referred to the T.H.I.E. Co. The substantial, simple and practical manner in which all the details are carried out, deserves our entire approbation. The whole installation is an excellent one, and finds great favour with all experts, as well as with the public.

"We give you this detailed explanation in order to prevent the misleading of the public by the article in your much read paper, and are convinced that you will correct such untrue statements made in the article in question.

"(Signed)

"BREMER PFERDEBAHN-GESELLSCHAFT."

The facts of the case are that the road has been running continuously ever since June 23rd, and during that time the five motor cars, with occasional tow-cars, have carried over 453,491 paying passengers, not counting other passengers whose tickets, paid for on other divisions of the line, have entitled them to continue the trip over the electric line, and not including those having season tickets or free cards.

There have been no interruptions to the service due to electrical causes.

Inasmuch as the Society of Engineers and Architects of Germany, after their general meeting in Hamburg, also visited the Bremen Exhibition in great numbers, and inasmuch as Bremen has been the seat of the annual meeting this year for the Physical Society of Germany, and the Exhibition itself being one of great merit, especially as to engineering details, has attracted many eminent technical men of North Europe, especially many practical street railway men, there has been ample opportunity for criticism and free expression of opinion regarding the tramway there, but in all the conversations that we have had with such judges, and all the notices that we have seen in the German press, adverse criticism has been lacking.

Thomson-Houston International Electric Co.

LOUIS J. MAGEE.

September 26th, 1890.

### Electricity v. Gas.

I have read with great interest the article in last week's ELECTRICAL REVIEW *re* "The Relative Cost of Gas and Electricity in Cotton Mills," and which, no doubt, many of your subscribers have also read; but do you not think that this is far from what the average maintenance would be? It strikes me that it is much

too low. Take, for instance, coal. Where outside of Lancashire would you be able to get coal at 5s. per ton average for 6 years? This is, in my opinion, extremely low and somewhat misleading. I also observe that the power is put down at £150, or £5 per H.P. I presume this is the engine alone, if so what is the boiler worth, and what is the depreciation thereon. I should also suggest that something should be taken from the engineer's account and put to the maintenance account, as I fail to see that the management of an installation of this size should cost practically nothing. Surely the time putting new lamps on alone should make a slight difference.

A. Handley.

September 22nd, 1890.

#### Tesla's New Alternating Motors.

The following communication, which Mr. Tesla has sent to the New York *Electrical Engineer*, he desires should also appear in the REVIEW:—

I hope you will allow me the privilege to say in the columns of your esteemed journal a few words in regard to an article which appeared in *Industries* of August 22nd, to which my attention has been called. In this article an attempt is made to criticise some of my inventions, notably those which you have described in your issue of August 22nd, 1890.

The writer begins by stating: "The motor depends on a shifting of the poles under certain conditions, a principle which has been *already*\* employed by Mr. A. Wright in his alternating current meter." This is no surprise to me. It would rather have surprised me to learn that Mr. Wright has *not yet* employed the principle in his meter, considering what, before its appearance, was known of my work on motors, and more particularly of that of Schallenberger on meters. It has cost me years of thought to arrive at certain results, by many believed unattainable, for which there are now numerous claimants, and the number of these is rapidly increasing, like that of the colonels in the South after the war.

The writer then good-naturedly explains the theory of action of the motive device in Wright's meter, which has greatly benefited me, for it is so long ago since I have arrived at this and similar theories that I had almost forgotten it. He then says: "Mr. Tesla has worked out some more or less complicated motors on this principle, but the curious point is that he has completely misunderstood the theory of the phenomena, and has got hold of the old fallacy of screening." This may be *curious*, but how much *more curious* it is to find that the writer in *Industries* has *completely misunderstood* everything himself. I like nothing better than just criticism of my work, even if it be severe, but when the critic assumes a certain "l'état c'est moi" air of unquestioned competency I want him to know what he is writing about. How little the writer in *Industries* seems to know about the matter is painfully apparent when he connects the phenomenon in Wright's meter with the subject he has under consideration. His further remark, "He (Mr. Tesla) winds his secondary of iron instead of copper and thinks the effect is produced magnetically," is illustrative of the care with which he has perused the description of the devices contained in the issue of the *Electrical Engineer* above referred to.

I take a motor having, say, eight poles, and wrap the exciting coils of four alternate cores with fine insulated iron wire. When the current is started in these coils it encounters the effect of the closed magnetic circuit and is retarded. The magnetic lines set up at the start close to the iron wire around the coils, and no free poles appear at first at the ends of the four cores. As the current rises in the coils more lines are set up, which crowd more and more in the fine iron wire until finally the same becomes saturated, or nearly so, when

the shielding action of the iron wire ceases, and free poles appear at the ends of the four protected cores. The effect of the iron wire, as will be seen, is two-fold. First, it retards the energising current; and, second, it delays the appearance of the free poles. To produce a still greater difference of phase in the magnetisation of the protected and unprotected cores, I connect the iron wire surrounding the coils of the former in series with the coils of the latter, in which case, of course, the iron wire is preferably wound or connected differentially, after the fashion of the resistance coils in a bridge, so as to have no appreciable self-induction. In other cases I obtain the desired retardation in the appearance of the free poles on one set of cores by a magnetic shunt, which produces a greater retardation of the current and takes up at the start a certain number of the lines set up, but becomes saturated when the current in the exciting coils reaches a predetermined strength.

In the transformer the same principle of shielding is utilised. A primary conductor is surrounded with a fine layer of laminated iron, consisting of fine iron wire or plates properly insulated and interrupted. As long as the current in the primary conductor is so small that the iron enclosure can carry all the lines of force set up by the current there is very little action exerted upon a secondary conductor placed in vicinity to the first; but just as soon as the iron enclosure becomes saturated, or nearly so, it loses the virtue of protecting the secondary, and the inducing action of the primary practically begins. What, may I ask, has all this to do with the "old fallacy of screening?"

With certain objects in view—the enumeration of which would lead me too far—an arrangement was shown in the *Electrical Engineer*, about which the writer of *Industries* says:—"A ring of laminated iron is wound with a secondary. It is then encased in iron laminated in the *wrong direction*, and the primary is wound outside of this. The layer of iron between the primary and secondary is supposed to 'screen' the coil. Of course it cannot do so; such a thing is unthinkable." This reminds me of the man who had committed some offence, and engaged the services of an attorney. "They cannot commit you to prison for that," said the attorney. Finally the man *was* imprisoned. He sent for the attorney. "Sir," said the latter, "I tell you they *cannot* imprison you for that." "But, sir," retorted the prisoner, "they *have* imprisoned me." It *may not* screen, in the opinion of the writer of *Industries*, but just the same it *does*. According to the arrangement, the *principal* effect of the screen may be either a retardation of the action of the primary current upon the secondary circuit, or a deformation of the secondary current wave with similar results for the purposes intended. In the arrangement referred to by the writer of *Industries* he seems to be certain that the iron layer acts like a choking coil; there again he is mistaken; it does not act like a choking coil, for then its capacity for maintaining constant current would be very limited. But it acts more like a magnetic shunt in constant current transformers and dynamos, as, in my opinion, it ought to act.

There are a good many more things to be said about the remarks contained in *Industries*. In regard to the magnetic time lag, the writer says: "If a bar of iron has a coil at one end, and if the core is perfectly laminated, on starting a current in the coil the induction *all along the iron* corresponds to the excitation at that instant, unless there is a microscopic time lag, *of which there is no evidence*." Yet a motor was described, the very operation of which is dependent on the time lag of magnetisation of the different parts of a core. It is true the writer uses the term "perfectly laminated" (which, by the way, I would like him to explain), but if he intends to make such a "perfectly laminated" core, I venture to say there is trouble in store for him. From his remarks I see that the writer completely overlooks the importance of the size of the core and of the number of the alternations pointed out; he fails to see the stress laid on the saturation of the screen, or shunt, in some of the cases described; he does not seem to recognise the fact that in the cases considered the

\* All italics are mine.

formation of current is reduced as far as practicable in the screen, and that the same, therefore, so far as its quality of screening is concerned, has no rôle to perform as a conductor. I also see that he would want considerable information about the time lag in the magnetisation of the different parts of a core, and an explanation why, in the transformer he refers to, the screen is laminated in the *wrong direction*, &c.—but the elucidation of all these points would require more time than I am able to devote to the subject. It is distressing to find all this in the columns of a leading technical journal.

In conclusion, the writer shows his true colours by making the following withering remarks: "It is questionable whether the Tesla motor will ever be a success. Such motors will go round, of course, and will give out-puts, but their efficiency is doubtful; and if they need three-wire circuits and special generators there is no object in using them, as a direct current motor can be run instead with advantage."

No man of broad views will feel certain of the success of any invention, however good and original, in this period of feverish activity, when every day may bring new and unforeseen developments. At the pace we are progressing the permanence of all our apparatus in its present forms becomes more and more problematical. It is impossible to foretell what type of motor will crystallise out of the united efforts of many able men; but it is my conviction that at no distant time a motor having commutator and brushes will be looked upon as an antiquated piece of mechanism. Just how much the last-quoted remarks of the writer of *Industries*—considering the present state of the art—are justified, I will endeavour to show in a few lines.

First, take the transmission of power in isolated places. A case frequently occurring in practice and attracting more and more the attention of engineers is the transmission of large powers at considerable distances. In such a case the power is very likely to be cheap, and the cardinal requirements are then the reduction of the cost of the leads, cheapness of construction and maintenance of machinery and constant speed of the motors. Suppose a loss of only 25 per cent. in the leads, at a full load, be allowed. If a direct current motor be used, there will be, besides other difficulties, considerable variation in the speed of the motor—even if the current is supplied from a series dynamo—so much so that the motor may not be well adapted for many purposes, for instance, in cases where direct current transformation is contemplated with the object of running lights or other devices at constant potential. It is true that the condition may be bettered by employing proper regulating devices, but these will only further complicate the already complex system, and in all probability fail to secure such perfection as will be desired. In using an ordinary single-circuit alternate current motor the disadvantage is that the motor has no starting torque and that, for equal weight, its output and efficiency are more or less below that of a direct current motor. If, on the contrary, the armature of any alternator or direct current machine—large, low-speed, two-pole machines will give the best results—is wound with two circuits, a motor is at once obtained which possesses sufficient torque to start under considerable load, it runs in absolute synchronism with the generator—an advantage much desired and hardly ever to be attained with regulating devices; it takes current in proportion to the load, and its plant efficiency within a few per cent. is equal to that of a direct current motor of the same size. It will be able, however, to perform more work than a direct current motor of the same size, first, because there will be no change of speed, even if the load be doubled or tripled, within the limits of available generator power; and, second, because it can be run at a higher electromotive force, the commutator and the complication and difficulties it involves in the construction and operation of the generators and motors being eliminated from the system. Such a system will, of course, require three leads, but since the plant efficiency is practically equal to that of the direct current system, it will require the

same amount of copper which would be required in the latter system, and the disadvantage of the third lead will be comparatively small, if any, for three leads of smaller size may perhaps be more convenient to place than two larger leads. When more machines have to be used there may be no disadvantage whatever connected with the third wire; however, since the simplicity of the generators and motors allows the use of higher electromotive forces, the cost of the leads may be reduced below the figure practicable with the direct current system.

Considering all the practical advantages offered by such an alternating system, I am of an opinion quite contrary to that of the author of the article in *Industries*, and think that it can quite successfully stand the competition of an direct current system, and this the more the larger the machines built, and the greater the distances.

Another case frequently occurring in practice is the transmission of small powers in numerous isolated places, such as mines, &c. In many of these cases simplicity and reliability of the apparatus are the principal objects. I believe that in many places of this kind my motor has so far proved a perfect success. In such cases a type of motor is used possessing great starting torque, requiring for its operation only alternating current, and having no sliding contacts whatever on the armature, this advantage over other types of motors being highly valued in such places. The plant efficiency of this form of motor is, in the present state of perfection, inferior to that of the former form, but I am confident that improvements will be made in that direction. Besides, plant efficiency is, in these cases, of secondary importance, and in cases of transmission at considerable distances, it is no drawback, since the electromotive force may be raised as high as practicable on converters. I cannot lay enough stress on this advantageous feature of my motors, and should think that it ought to be fully appreciated by engineers, for to high electromotive forces we are surely coming, and if they must be used, then the fittest apparatus will be employed. I believe that in the transmission of power with such commutatorless machines, 10,000 volts, and even more, may be used, and would be glad to see Mr. Ferranti's enterprise succeed. His work is in the right direction, and, in my opinion, it will be of great value for the advancement of the art.

As regards the supply of power from large central stations in cities or centres of manufacture, the above arguments are applicable, and I see no reason why the three-wire motor system should not be successful. In putting up such a station, the third wire would be but a very slight drawback, and the system possesses enough advantages to over-balance this and any other disadvantage. But this question will be settled in the future, for as yet comparatively little has been done in that direction, even with the direct-current system. The plant efficiency of such a three-wire system would be increased by using, in connection with the ordinary type of my motor, other types which act more like inert resistances. The plant efficiency of the whole system would, in all cases, be greater than that of each individual motor—if like motors are used—owing to the fact that they would possess different self-induction, according to the load.

The supply of power from lighting mains is, I believe, in the opinion of most engineers, limited to comparatively small powers, for obvious reasons. As the present systems are built on the two-wire plan, an efficient two-wire motor without commutator is required for this purpose, and also for traction purposes. A large number of these motors, embodying new principles, have been devised by me and are being constantly perfected. On lighting stations, however, my three-wire system may be advantageously carried out. A third wire may be run for motors and the old connections left undisturbed. The armatures of the generators may be re-wound, whereby the output of the machines will be increased about 35 per cent., or even more, in machines with cast iron field magnets. If the machines are worked at the same capacity, this

means an increased efficiency. If power is available at the station, the gain in current may be used in motors. Those who object to the third wire, may remember that the old two-wire direct system is almost entirely superseded by the three-wire system, yet my three-wire system offers to the alternating system relatively greater advantages than the three-wire direct possesses over the two-wire. Perhaps, if the writer in *Industries* would have taken all this in consideration, he would have been less hasty in his conclusions.

Nikola Tesla.

New York, September 10th, 1890.

#### Re Mr. Varley's New Photometer.

I have been much interested in reading the account of the new photometer invented by Mr. F. H. Varley; and it is almost unnecessary to say that it is superior to the older forms in several respects; but as I have been engaged in experimenting for some time past over a similar project, I trust my intentions may not be misunderstood in querying the absolute "mathematical" accuracy with which measurements may be conducted by means of this apparatus.

Errors which exist in the Bunsen photometer would, I believe, be found to occur, although possibly to a far lesser extent, in this instrument, due to the following causes:—

- (1.) Spectral disparity between the two radiants.
- (2.) Irregularity of luminous intensity of the standard.
- (3.) Inability of the human eye to estimate exactly when the neutralising action of the discs comes into play, for, it must be remembered, that in estimating the difference between, say, a white and a pale grey, the eye is not possessed of sensitive properties in a very exalted degree. This by itself would be but a trifling error, but might become more important if error No. 1 existed.

(4.) Faulty adjustment of the mutual screen distance in regard to the two radiants.

(5.) Slight external vibration or irregularity of rotation of the discs would tend to increase this error when the light to be measured has great luminosity compared with the standard, owing to the necessary disparity of slot width in such cases.

It will, I trust, be conceded that my intentions in pointing out what defects I believe to exist in this apparatus are not in any way due to mercenary ends, as I am not very desirous of commercially developing the instrument whose completion I expect shortly, and whose perfection (if it be found to possess such) is largely due to the friendly critique of the design of a former apparatus by Mr. S. A. Varley, the brother of the inventor of the apparatus under discussion, which differs entirely in design from my own.

Ralph Richards.

#### Electrical Heterodoxy.

Your correspondent, Mr. Henry Sutton is a maker of logomachies, and something more than this. He writes: "It does not follow that because we speak of + and — electrification and polarisation that we believe, or even assume, there are two electricities." Faraday was not so foolish as to attempt to describe that which he called induction or polarisation of glass without assuming that there were two electric forces to produce the effect; but what Mr. Sutton means by induction and polarisation of glass without assuming that there are two electric forces to produce them, is beyond my comprehension.

Mr. Sutton writes: "Assuming the spark an evidence of conduction, and its passage an evidence of current, then if the conduction is absolute, the glass should be perforated." Mr. Sutton would not have written this

if he had studied the difference between Faraday's theory of electricity and mine; but Mr. Sutton has rushed into print without reading my book. Glass is a porous body; through some kinds of it electricity passes with perfect freedom because the pores in it are so large that the particles of the electric matter can pass through without obstruction, and, consequently, without disrupting the glass; but there are other kinds of glass the pores in which are not so large as to allow all the particles of a current of electricity to pass immediately through without some obstruction, and hence a Leyden jar becomes charged. The reasons for this I have assigned at length in my book, to which I must refer Mr. Sutton.

James Johnstone.

#### A Recommendation.

An Electrical Directory is just now collecting its information amongst the electrical and allied trades, but I think it will be news to the many eminent inventors and manufacturers who by right are included in its pages to learn that, judging by the issue of last year, they are exposed to classification with such specialists as Mr. C. B. Harness and Mr. Edward Moross, and such leading manufacturers as Messrs. Constantine and Jackson, whose announcements are usually to be met with in those public edifices occupying advantageous sites in the centres of many of our principal thoroughfares, either above or below the surface.

I would take this opportunity of recommending the author and compiler of this directory to delete such persons, it would hardly make his book less *burly*.

Anti-Harness.

#### Ship Wiring.

The writer of the comments on the heating of the electric light leads in the ss. *Etruria*, is evidently not practically acquainted with either single wiring, double wiring, or any other wiring systems for ship lighting. I have fitted out over a hundred steamships with electric light, some double wired and some single wired—mostly single wired—and my experience goes to prove that single wiring is the most expensive system, when carried out properly, and is very much safer as regards fire risks and breakdown.

For single wiring on board ship, only iron armoured vulcanised rubber insulated copper wires should be used, with malleable cast iron junctions; lead sheathing and wood casing is not good enough, except for branches to each lamp in the cabins, saloons, &c. As to fuses, I have known instances where a No. 20 lead fuse had been replaced by a No. 16 copper wire, and no doubt many fusible plugs are rendered valueless by careless replacing of the fuse by heavy copper wire. Everyone knows that a short-circuit on a ship is not at all dangerous if there are workable fuses in all branches, and the danger is all in either not having fuses all or in having a fuse spoiled by the insertion of a good thick copper wire.

Cheapness has ruined the business of ship lighting. In fact, in some cases, it is advisable not to offer for such work at all rather than put in the cheap installations that are sometimes desired; but, in fact, a single wired installation is dearer than a double wired one, the saving in copper being more than balanced by the extra labour in hole boring, and by the cost of iron wire sheathing and iron junctions. The fittings are much safer having only one wire in them, and centre contacts can be used throughout, the insulation being nowhere subjected to cutting or abrasion as is the case in double wired fittings, where the wires are pulled through and fixed into holders by screws.

R. Kennedy.

## THE LABOUR QUESTION.

TRADES unionism, which has given us many varied and altogether unpleasant experiences, has seldom shown its true character so distinctly as during the last week, and it is somewhat humiliating, as Englishmen, to be obliged to confess that the qualities of the labouring man, as a unionist, most prominently brought into notice—that is to say, if he be rightly represented by his spokesmen—are those of a bully, a sneak, and a perverter of the truth. By this time there must be but very few persons sanguine enough to still place any faith in the word or bond of the British workman. This is not very pleasant talking, but it is impossible to come to any other conclusion after a consideration of the events of, let us say, the last twelve months. For the moment, indeed, difficulties seem to be tided over, but at any instant and, as it is now made public with almost brutal cynicism, without any preliminary warning, employers may find their works bare of men, their cargoes awaiting to be unloaded, their machinery standing idle, and their steamers detained for want of coal.

It would really seem hopeless to expect the arrival of the day when it will be brought home to the labouring man that if capital be prevented from obtaining labour in one locality it will surely succeed in meeting with it elsewhere, and that, just as certainly, if capital be debarred from an outlet in one direction, it cannot be idle, but must seek a course for its natural functions under other more favourable circumstances and conditions.

The difficulties with which trades unions are seeking to surround the free employment of labour and an untrammelled development of industry, can have but one result—the alienation of capital, and consequently of work; indeed, the present effects are serious enough, without borrowing any possibilities from the future. The docks and river strikes have already diverted an enormous amount of business from the Thames, and, with more particular reference to that trade organisa-

tion which has been trying to play a lone hand, large contracts have been recently made with firms in the Canary Islands for the supply of coal for a long period to certain important lines of steamers. This is a more serious matter than would at first appear, for although it is at present only a question of coaling ships, it is the first step towards the building up, at the expense of the labouring man in England, of alien enterprise and industry.

Amidst the labouring population there surely must be men of clear sight and sound judgment, and it seems strange that these cannot appreciate the fact that the cry of “capital *versus* labour” is nothing but a catchword, and beyond serving, for the want of a better, the purpose of a party-cry, is absolutely meaningless. Capital must, perforce, be brought into utilisation by means of labour, and if muscle cannot be depended upon to fulfil its engagements, one consequence, among others, overlooked to a great extent because the effects are not immediately appreciable, is that the incentive to perfecting labour-saving appliances receives increased stimulus.

No one could for a moment attempt to deny the misery existing among some of the working classes, and it is brought into the stronger relief from the squalor of their surroundings and the utter improvidence of their habits. The stern and immutable law of nature that the weakest must succumb in the struggle for existence is nowhere so painfully evident as in our teeming population, our overcrowded districts. The labouring classes can no more expect to be exempt from this law than any other order; the strongest, mentally or physically, must eventually push to the front. Any attempt to bolster up the weak and incapable can only result in the lowering of the general average, and this is precisely what will happen if the inefficient workman is to be paid the same as the capable. The survival of the fittest may sound a heartless axiom, but it indicates the only sound and healthy condition of society. The bringing of all labour to an equality in remuneration

is an attempt to promote the welfare of the ignorant and thriftless at the expense of the competent and ambitious; it would eliminate competition, which is the life and soul of all progress, individual or national; and reduce mental and physical faculties to a dull dead level of mediocrity.

The subject is one we have repeatedly brought before our readers, and, unfortunately, the occasion is too frequently given to us of reverting to the ill-directed struggles of the working man to assert his independence, and to the attempts of party leaders to subvert the natural laws of supply and demand to illegitimate ends.

### MORE ELMORE.

"IT looks as if Baron Grant is coming to the fore again. We understand that the Baron has had a good deal to do with bringing out some of the Elmore copper companies. City men used to say that he could draw up a prospectus better than any man in London."

The *Star* of Saturday last is responsible for the foregoing.

If any explanation were needed for again referring to the subject, it would suffice to say that the Baron is not likely to leave a fruitful field untilled.

"Kings can titles give, but honours can't,  
Title without honour is a barren grant."

We are sorry that the Baron has taken electrical ventures under his wing. Mines were at one time his favourites. Through the "Emma" the public lost a considerable sum, though very important names were on the board. It was, we believe, the action of Rubery v. Grant which led to the fall of a Sampson, and journalists will not soon forget the circumstances which preceded the placing of "Printing House Square" at the head of the *Times* money article. Association with the Baron has hitherto boded ill.

So long as Elmore companies can be successfully floated, Elmore companies will be issued. We hold it to be the duty of those who can in any way throw light upon the subject not to spare any trouble in doing so. The bases of the issues are prospectuses, reports, and patents. We purpose examining these in their order, with a view to discover their salient features. To-day we deal with the prospectuses.

Following is a list of the companies already floated, with the amounts of capital issued, and the prices paid for their rights:—

Company.	Capital issued.	Purchase Price.	
		Cash.	Shares.
Elmore Co. (British) ...	£140,000	£53,400	£46,600
Elmore Wire ...	200,020 }	75,000 }	20
Premium ...	100,000 }	50,000 }	
Elmore Co. (Foreign and Colonial) ...	120,000	80,000	30,000
Elmore Co. (French) ...	200,000 }	83,500 }	66,500
Premium ...	33,375 }	33,375 }	
Elmore Co. (Austro-Hungarian) ...	200,000 }	50,000 }	50,000
Premium ...	37,500 }	37,500 }	
	£1,030,895	£462,775	£193,120
		£655,895	

It will be seen that of the capital issued more than half has been paid away for rights, and that the vendors have a preference for cash. It may be noted, too, that the vendors to the Wire Company were content with half the premiums. The vendors to the French and Austrian Companies took all the premiums.

The patentees, or original vendors, received in cash and shares from the British and Foreign and Colonial Companies £210,000.

The British Company paid £100,000, and received from the Wire Company, for a partial license, £125,020.

The Foreign and Colonial Company paid £110,000, and received from the French and Austro-Hungarian Companies £320,875.

The five companies have 29 directorships. Fifteen gentlemen fill these. Mr. William Elmore is a director of four companies. Four other gentlemen are directors of four; two of two.

Messrs. F. E. and A. S. Elmore are either joint works managers, or joint consulting metallurgical chemists, to all the companies, without exception.

One gentleman acts as secretary of all the companies, without exception.

The prospectuses are nearly all alike, as we pointed out last week. The compilers of the original must be credited with having fairly exhausted the subject, including the Bessemer comparison. One of those points which strike us, on a reperusal of the prospectuses, is the sudden way in which a series of conjectures or estimates becomes "the above plain statement of facts."

Tracing the estimates in the later prospectuses back to their source, we find that in the Wire Company's prospectus it is stated that the estimate of cost of manufacture has been prepared by Mr. William Elmore.

It therefore comes down to this, that the figures upon which the directors base their calculations are the figures of one of the original vendors; the managers of the works in which any practical work may have been done being also among the original vendors.

The question we are naturally inclined to ask the directors is, whether, in a matter of such importance, it is altogether wise to base so much on the estimates of those who might reasonably be expected to develop a sanguine temperament.

A Record.

"SINCE then electricity comes not from the sun as from a heated body, it comes from its home the bowels of the earth. When God first created everything beautiful in its time (Eccles. iii.) as well for man's needs as to reflect his own glory, He placed latent heat, electric fire, in the centre of the earth as its nucleus, to radiate from the centre to the circumference, and to thereby hatch and vivify and cause to grow everything to which He had imparted life." "When the collapse of the eggshell crust (of the earth) comes, it will not be from the atmosphere from above driving it into a vacuum from below, which could not exist, but the presence of the fires and electricities of the earth, chockfull of them,

overcoming the resistance of the lighter electricity in the atmosphere above and its vacuums and universal cyclones." The above are not extracts from the works of Roger Bacon, or Paracelsus, but from a letter written by T. W. Christie, B.A. (Camb.), to the *Liverpool Courier* of Wednesday last, with the view of expounding to the readers of that journal, "where electricity comes from." In the same letter Mr. Christie propounds the theory that the sun is not hot, but shines and warms by reflected light and heat. We should not be surprised to hear that Mr. Christie believes that the earth is flat, or that the earth is the centre of the solar system. Considered as a sample of "newspaper science," Mr. T. W. Christie's letter has, we think, made a record.

Elmore Wire.

A WELL-KNOWN electrical expert who, if we mistake not, has taken a prominent part in testing Elmore copper wire, is stated to have said that under precisely similar mechanical conditions its conductivity is better by 2 per cent. than any other copper, electrically deposited or otherwise, with which he was acquainted. This slight difference is not likely to cause rival manufacturers much serious inconvenience, as we have previously pointed out a manner by which compensation may be made for any such small deficiency in conducting power. Moreover, we have yet to learn at what price this "extra high conductivity" wire can be put on the market.

National Telephone  
Company. A High-  
handed Policy.

A MR. ERSKINE MUIRHEAD, writing to a provincial newspaper, complains of a high-handed proceeding on the part of the National Telephone Company. It appears that Mr. Muirhead, at the request of the company, brought over to this country several telephones of the Ader and Berthon type; immediately afterwards Mr. Muirhead received a note from the company saying that the telephones in question were a direct infringement of their patents, and unless they were returned to France at once an action at law would result. If the facts are as stated, a more gross case can hardly be imagined; but we cannot but think that Mr. Muirhead has not fairly represented what has actually happened, for it would only be necessary to prove in Court that the company had invited Mr. Muirhead to bring over the instruments, for the action to be dismissed with costs. Mr. Muirhead also complains that, as a consequence of the dispute apparently, he was cut off from the Telephone Exchange, although he had signed the usual contract, under which he had the right to a further year's use of the privilege. The cause of all this is stated to be that the Ader-Berthon telephone is much superior to the existing apparatus, and that were it once tried by the public there would be a general demand all round for its adoption. Mr. Muirhead states that "as the patent will expire in a few days, he will be glad to fix a pair in the office of the provincial journal in question;" he does not state to what patent he refers, but inasmuch as the Edison patent, which has practically been held to cover the use of carbon, does not expire till July of

next year, it is difficult to see what right he has to fix the telephones in question in a few days. At the commencement of his letter Mr. Muirhead states that the Ader and Berthon telephones are in daily use, speaking between towns over 600 miles apart, this, we presume, being brought forward as an argument for the superiority of the instrument; as a matter of fact, it ought to be pretty well known now that to speak over 600 miles is not such a very marvellous feat, as the question is not one of instruments but of a sufficiently large copper wire. The Blake instrument, as used by the telephone companies, is not a satisfactory apparatus, as it requires careful adjustment to make it work properly; there are plenty of microphonic transmitters of simple design which are more efficient and require no adjustment whatever, but to substitute these would involve very great expense.

The Elmore  
Copper Company.

THOUGH our remarks in another column bear on some of the points raised by "a shareholder," we think it may be well to deal with them here *serialim*. We gave, as we think, good reasons for raising the question of justification for companies in some countries, even assuming the success of the process—say, in England—so we need not follow our correspondent into the regions of political economy. We are awaiting the proofs which our correspondent takes for granted in the next paragraph, and we are obliged to differ with him in his logic of criticism. "A shareholder" has reached the nutshell; we want to get at the kernel! We do not doubt that Elmore shareholders will consider our six columns might have been devoted to better purpose; at the same time, they will perhaps allow that we are the better judges on that point, for we attach no importance to the company's guarantees of their manufactures at present. Our correspondent should be aware that we do not condemn without enquiry. We are enquiring, and we have not condemned the invention, but we do condemn most strongly the promotion of sub-companies, and the payment of large sums for the invention in its present stage. "A shareholder's" second point may be left to the common sense which settles things "on evidence which cannot be fairly disputed." The statement that Mr. Clark was not referring to Elmore copper we take to mean, also, that he was not referring to copper "made in the same way as Elmore copper." If this be so it is of value, and we are much obliged to our correspondent for pointing it out. We shall bear it in mind in our further enquiries, but so far as our last week's article is concerned Mr. Clark's evidence may be removed from it entirely without modifying in any way the conclusions at which we arrived. We attach no importance whatever to the fact that Mr. Parker has become a shareholder. Without being quite sure that we understand the intent of his concluding paragraph, we imagine that "a shareholder" thinks that it will take considerable time and much puffing of Elmore copper to bring about the impending revolution. So do we! There is no necessity for "a shareholder" to write himself down a fool and say we called him so. We did not say that all Elmore shareholders were fools. We do not think they are. Something depends on the companies they are in, and we are not sure whether some of them may not deserve a different appellation, which we hold in reserve.

ON THE PROTECTION OF BUILDINGS  
FROM LIGHTNING.\*

I MAY, perhaps, be permitted to state in a few words why I have chosen lightning for the subject of my paper. My reason is that considerable uncertainty is reputed to exist amongst architects, builders, engineers, and others, who are occasionally, although not professed electricians, called upon to erect lightning conductors, and particularly because I have had quite recently two cases illustrative of this suspected uncertainty brought forcibly to my notice, one of the two cases being one in which a number of persons narrowly escaped with their lives. It seemed to me, therefore, that lightning conductors offered a meet and appropriate subject for discussion by this Association.

The first case occurred in connection with this present exhibition. The electrical and lighting committee decided that both the old and new systems of protection should be illustrated practically, so the chimney of the boiler house was ordered to be protected by a stranded copper rope of the ordinary type, and the minarets of the main building by iron wire, according to a design kindly furnished by Dr. Oliver Lodge. The erection of the chimney proceeded with unexpected celerity, and when the committee went to specify the precautions they wished to have observed in earthing the conductor, they were informed that the conductor was up, earthed and finished. The builder assured them that it was "all right;" but, appreciating the ridiculous figure that would be cut by an electrical committee were a chimney under their special care struck and injured, it was resolved to do violence to the builder's feelings, and dig up his earth. It was found that the end of the conductor was only a few inches below the surface, and was loosely embedded in builder's *débris*. That was the first case, and was detected and remedied in time. The second was only revealed by an actual visitation of lightning.

Last month, during a severe thunderstorm, and while it was raining very heavily, the inmates of a gentleman's house were startled by a tremendous report. Simultaneously a great light was seen in various rooms by different people. The house is peculiarly situated, being erected on the slope of a rocky hill, about 600 feet above the base, and some 1,000 feet below the summit. It is fitted with the electric light, all the leads being within the building. A telephonic connection exists with the stables in the valley below, some 1,000 yards distant; it consists of two copper wires thickly insulated with gutta-percha, which are used as a metallic circuit. They are underground the whole way, being laid in a wooden box buried in a trench, except at one point, where they cross a stream in an iron pipe laid in its bed. Within the house and stables the wires are led to the instruments in wooden boxing.

When the flash occurred light was seen in almost every room of the house. A tailor employed in one of them asserts that light played about his thimble and scissors, and the cook is positive that a flame appeared around her kitchen grate. The housekeeper, who was seated in her room, says she heard a faint rustling sound in the direction of one of the electric lamps. She turned her head, and was immediately conscious of a blaze of light which seemed to dart from the lamp to the grate. The next thing she remembers was finding herself on the floor, unhurt, but greatly terrified. She picked herself up and, strange to relate, made her way to a mirror, but for some minutes was unable to distinguish her reflection in it. The lady of the house saw, or believes she saw, a ball of fire, of a deep red colour, in the dining room, but others present were aware only of a dazzling light of no defined shape, which appeared to some of them to play for an instant over the wall paper, which is embossed with metal.

At the stables end a groom states that a ball of fire, this time of a white colour, about the size of a cricket ball, appeared in the middle of the room and instantly exploded with a report that stupified and deafened him, and the effects of which he felt in his ears for several days. The light from the exploded ball seemed to diffuse itself in all directions, but he was conscious of a more intense action in the neighbourhood of the telephone.

An examination showed that the safety fuses of the electric light system were melted. The hinged door of the box containing them, which was situated about 4 feet from the telephone on the same wall, was knocked off and thrown to a distance. It was much scorched inside. The telephone wires were fused in three different places, once in the iron pipe in the bed of the stream, once midway between the stream and the stables, and once a few yards on the house side of the stream. At the second place the wooden boxing was completely destroyed for about 6 inches; at the third its bottom only was knocked out. In the stables the boxing was blown off the wall, but the wires escaped injury, as did the telephones at both ends. Where fused the wires presented a sharpened or pointed appearance on the sections furthest from the house and a rounded shape on those nearest it. In the stables, not far from the telephone, some wires, apparently connected to the earth, extended partly up the wall. They are said to have been used in connection with an A B C telegraph instrument which was formerly installed there.

At the moment of the discharge—as nearly as can be ascertained—in the house, two bullocks grazing in the fields two or three miles off were struck dead. This is a most interesting fact, for it tends to substantiate what has often been asserted and sought to be established by evidence such as this, that lightning discharges frequently, if not invariably, are double; that at the moment a flash takes place from clouds to earth at one place another ascends from earth to clouds at another, a phenomenon to which the name of back or return stroke has been given. It is indeed necessary that something of the kind should happen if the comparison between lightning and Leyden jar phenomena and ordinary electricity generally is to hold good, for a circuit of some kind is a necessity. A vivid flash between clouds and earth at one point only argues a circuit completed elsewhere—that is to say, a good conducting region—an absence of a dielectric, between earth and clouds at another, just as the arc of an electric lamp signifies that there is a conducting circuit, invisible and lengthy perhaps, but still a circuit, connecting the carbons between which it plays. Such a condition may exist during rain to an extent sufficient to permit of invisible conduction over a considerable area, or an actual waterspout such as is common in the tropics may form the conducting link, leaving forcible rupture of the dielectric to take place at one point only. Absence of such a conducting region necessarily means two dielectrics, two ruptures, and two vivid and co-existent, although perhaps, and probably, widely separated flashes, stroke and back stroke. It is reasonable to suppose that lightning, at least sometimes, may be merely a neutralisation by means of the clouds of opposite tensions existing at different points of the earth's surface. As soon as the cloud is long enough to cover both points, and low enough for the tensions to overcome the resistance of the intervening air, the neutralisation takes place, the cloud simply acting the part of the discharging tongs between the knob and outer coating of a Leyden jar. Lightning usually occurs after a spell of sultry weather when there is an absence of moisture, and consequently of conductivity in the atmosphere. In damp weather the necessary neutralisation between different parts of the earth's surface takes place—according to this hypothesis—constantly and silently, for there is no longer a dielectric resistant enough to prevent it.

It proved that the house, an extensive one, is largely roofed with lead, and has several iron spires which, at their lower extremities, are in contact with the lead of

\* Paper read at the Edinburgh International Exhibition, September 5th, 1890, before the East of Scotland Engineering Association, by A. R. Bennett, Vice-President.

the roof. The highest spire was found, after the storm, to be bulged and blackened at the junction of the iron with the lead. There are numerous metal rhones or drainpipes down the walls for carrying off the rain water. These are in contact with the lead-work of the roof above, but no provision is made for earthing them below—in fact, they are built into brick drains. When I add that there is no lightning conductor, and that the house is built on a thin layer of soil covering rock, it will be seen that—the existence of the telephone wires being taken into account—all the elements necessary for a first-class catastrophe were present. The absence of a conductor was accounted for by saying that when the house was built the architect stated that one was unnecessary. The proprietor was especially desirous of knowing how the electric light and telephone wires, which were wholly under cover and cased in, came to be struck. The explanation is not difficult. As is well understood, lightning is a discharge between two areas (these areas corresponding to the coatings of a Leyden jar) highly charged by electricity of the opposite signs. The clouds usually form one of these areas, and a high or prominent object on the earth the other. The principal path of a discharge is always that of the least resistance, or best conductivity, although partial discharges may likewise occur simultaneously by less perfect routes, and the discharge takes place as soon as the accumulated tension is high enough to overcome the resistance between the areas. A high point on the earth's surface is generally selected by the lightning, because whatsoever its nature it is usually, owing to the presence of moisture on its surface or in its pores, a better conductor than the air surrounding it. If it is a perfect conductor, or supports a perfect conductor of sufficient capacity in connection with the earth and with all adjacent metallic masses, the discharge passes from its extremity to its base without developing any noticeable phenomena; at any rate, nothing which is likely to cause danger to life or property, although it has been asserted that in the case of a very violent flash side discharges from the conductor of dangerous moment occur, in spite of the best earth connection. This, however, has been inferred rather from laboratory experiments than actually proved. If the precautions which I shall endeavour to prescribe and impress upon you as necessary are faithfully followed, such side discharges, should they happen, would probably be of inconsequence. A flash may very likely leap from the conductor to neighbouring masses of metal, if these are connected to earth and not to the conductor, especially if the earth of the conductor itself is a poor one; but so leaving them without a metallic link to the conductor would be a trifling with experience. On the other hand, if one or more sections of bad conductivity intervene between the summit and the earth, the discharge, although it will pass, will no longer do so harmlessly, but will develop explosive violence at the badly-conducting gaps. Its general course will still be the path of least resistance, but it may fly to and traverse any metal that lies in anything like a direct line between the summit and the earth, even if that metal only offers a path of a few feet. This tendency to leave the conductor will be increased proportionally as the earth connection is imperfect, a fact that will account, in the case under consideration, for the lightning striking the electric light wires; they, although covered and unconnected with the earth, offered the path of least resistance for a portion of the distance, and formed a connecting link between the point at which the lightning entered the dwelling and the point at which it left.

The enquiry seemed to indicate a discharge from the valley to the clouds *via* the telephone wires, electric light leads, chimneys and spires, the intervening air spaces within the house being jumped. The lightning, on this assumption, entered the wires at the stables by leaping from the old telegraph earth to the telephone terminals, and by piercing the insulation at and on each side of the stream. Arriving at the house, it jumped from the telephone terminals to the box containing the

electric light fuses, and thence travelled by the leads into every room in the house. There it jumped to grates, pipes, and other metallic masses, and so to the metal of the roof, and away. A noteworthy point, and one which is replete with instruction to electricians is, that had the house not possessed telephonic connection with the valley it might, owing to its position on a badly conducting rock, have escaped altogether; and had it not had electric light and bell leads in every room it still might have escaped in spite of the telephone wires. On the other hand, had not such a golden bridge as was offered by the leads existed, a leap from the basement to the roof through the body of the house might have been attended by utterly disastrous consequences. But the accident does not teach that we should deny ourselves the advantages attendant on telephones and electric lights. It teaches rather that these conveniences may be a source of danger if inconsiderately and carelessly fitted, just as gas or stoves or lamps may become centres of danger if ignorantly or recklessly dealt with. When telephone wires, and especially metallic circuits, are taken into a building they should be fitted as near the point of entry as possible with a good lightning discharge. This necessity I recognised several years ago as a consequence of more than one accident, since when all metallic circuits constructed by the National Telephone Company have been so fitted. Such a discharger costing only a few pence, would in all probability have shunted the lightning to earth, and the inmates of the house might not have even been aware that a discharge had taken place. Telephones working with an earth return do not require such care as metallic circuits.

A discharge of lightning through a conductor may be roughly illustrated by hydraulic analogy. Let us suppose a long perpendicular pipe with a number of lateral holes at intervals, its bottom extremity opening into a large empty cavity. A mass of water caused to fall suddenly into its upper end would descend through the pipe into the cavity, and having no resistance but the friction of the pipe and the resistance of the air in the pipe to overcome, it would so fall without any, or but little, of the water escaping through the lateral holes. This answers to a lightning conductor of sufficient capacity having a good earth. A pipe of small diameter opening into a large cavity would represent a conductor of insufficient capacity though with a good earth. Through this thin pipe the water could only flow comparatively slowly, and the tendency to leakage through the lateral holes would be considerably increased.

Now, imagine a large pipe with an obstacle placed at its bottom so that the diameter is reduced one-half, or a large pipe opening into a cavity incapable of containing the water let down; then the water descending with a tremendous impact is partially stopped by the obstacle, or by the filling up of the cavity. The water will rebound and spurt violently out of the lateral holes. This corresponds to a conductor of sufficient capacity connected to an insufficient earth, and the effects will be exaggerated proportionally as the aperture at the bottom is reduced. If the same pipe is taken with the bottom end plugged up, the stoppage and spurting of the water will be greatly augmented, and perhaps the pipe will burst from the suddenly exerted lateral pressure. This answers to a conductor with a very imperfect earth. The analogy is striking here; the water, like the electricity, is seeking earth, its lowest level, but failing to find it through the pipe, spurts or bursts out laterally, and then recommences its descent by the nearest channel it can find. The water may have to turn corners and run down flights of stairs on the way, so the electricity may have to avail itself of anything conducting whether it lies directly in the path or not.

I now propose to detail the recommendations I have made with the view of preventing a recurrence of the accident at this particular house. The example is a peculiar one in more than one respect, but still the recommendations embody the precautions which, with variations due to local surroundings, are necessary in

every case. The main object is obviously to provide a path of small resistance between the roof and the nearest earth. Owing to the rocky foundations of the house, this would seem to be at the stream in the valley and its vicinity, as the unusual mercy of a pioneer flash has clearly enough indicated.

The leaden roof with its spires which rise above everything may be left as it is, but seeing that rarefied air and soot are both conductors—comparatively poor ones, it is true, but still almost infinitely superior to air at the normal pressure—and that there are something like 40 chimneys opening above the roof, it is obvious that, taken collectively, the chimneys, especially when fires are on, present a conducting surface of very large area, and consequently of low resistance between the interior of the house and the atmosphere above it. When fires are burning this conducting surface may extend, in the shape of a column of rarefied air, considerably above the highest spire. To prevent the electricity selecting this conducting path of chimneys in parallel a better one must be provided, and this can fortunately be accomplished, as pointed out by Dr. Lodge, by erecting a skeleton cage of wire provided with a few pointed upright pieces above each group of vents, so that it may be enveloped by the rarefied air ascending therefrom. Each cage should have a soldered connection to the leaden roof, or by means of an iron wire direct to one of the conductors. These conductors may consist of at least four, preferably more, galvanised iron wires, No. 4 B.W.G., carried from soldered connections with the metal of the roof to the ground at as many different parts of the house, say at each corner, and at convenient intermediate points, and thence continued without break of continuity, and buried without boxing in a trench dug close to the boxing containing the telephone wires as far as the stream in the valley. The stables should be similarly treated, all the metal ridges of the roof, gutters, &c., being joined together by wire, at least one point projecting above everything else, and thence by means of two No. 4 wires laid in a trench also as far as the stream. There the water should be temporarily dammed back or diverted, and a hole excavated in the bed of the stream some 3 feet deep by 3 feet square. Into the hole a few bushels of retort carbon from a gasworks should be rammed; some 12 feet of each of the six iron wires—four from the house and two from the stables—should be coiled upon the carbon, then some more carbon well rammed down. Finally, the hole should be filled by well-rammed soil (not rock), and the water allowed to flow over it. If inconvenient to dam or divert the stream, the hole may be dug at one side of the water, and the water admitted over it when completed. There will then exist from the highest point of the house to the highest point of the stables a conductor making good earth at one place at least, and as good as the nature of the soil will permit at all others along the route, which is approximately that of the telephone wires. In the presence of such an arrangement, there would be no inducement for electricity to jump through several feet of air, and pierce thick gutta-percha insulation to invade the telephone wires. Further, in the house all systems of pipes or other masses of metal, such as grates, boilers, &c., should have connections with at least one of the conductors. Such connections may be of No. 5 B.W.G. galvanised iron wire, and should be soldered wherever possible. Of course, neither the electric light nor the electric bell nor the telephone wires can be so connected without interfering with their proper functions. This is a little unfortunate, but they may be dealt with by encasing a couple of feet of each of them in metal pipes, with India-rubber or porcelain rings between the leads and pipe, so as to make actual metallic contact impossible, while, at the same time, providing the shortest possible path for lightning between the three sets of leads. This would be attained by connecting the three lengths of pipe together and to the conductors by means of a No. 5 galvanised iron wire, soldered. In addition, the telephone wires should be fitted with an ordinary discharged at their place of entry. The object of these

branch connections is, of course, to prevent any jumping in the house, whatever may happen in the future. If the main earth connection became insufficient from any cause, the lightning would again make for the stream *via* the telephone wires; but if all metallic masses in the house, and the light and telephone wires, are treated as described, it would do so without any dangerous discharge. The only jump would be across the air space between the tubes and leads inside them and through the insulation, and this would be entirely harmless.

I recommend iron wire because—for the theoretical reasons adduced by Prof. Hughes and Dr. Oliver Lodge, into which I have no time to-day to enter, and with which many of you are no doubt perfectly familiar—iron is now widely admitted to be as effective as copper for currents appertaining to the character of lightning, and because iron has been employed habitually in America, in France, and elsewhere for a long period, and there is no evidence forthcoming to show that the percentage of accidents in those countries has been greater than in Great Britain, which has hitherto adhered rigorously to copper. True, some authorities still advocate the use of copper, but the greater cost of that metal precludes its employment so liberally about a building as could be wished, and when the greatest use has to be made of a certain sum, I consider, theoretical reasons apart, that it is beyond comparison wiser to invest that sum in six or eight iron conductors than in one or two copper ones. Copper would be preferable, on account of its greater durability when buried, but still galvanised iron will endure for years when so treated. Theoretically, a conductor of flat section like hoop iron would be better than wire, but it is more liable to decay. In addition to such conductors as described being fitted, the existing drain pipes should be connected to the roof by soldered wires or bands, and connected at the lower extremities to the conductors by a No. 5 galvanised iron wire, carried round and soldered to each of them; and a flagstaff standing about 20 yards from the house should have an iron wire run up it and connected to the conductors. In fixing the cables, sudden bends or changes of direction should be avoided. If all these precautions are taken, and the connections are examined from time to time, and repaired when necessary, the chances of another visitation from lightning will be very remote.

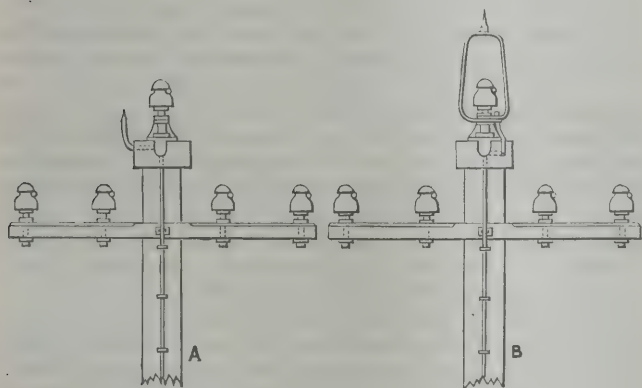

As before remarked, the recommendations are designed for a special case, and would not be applicable in all their details to many others. Still, to secure immunity from lightning, certain invariable precautions have to be taken in all cases. These are specially, firstly, having at least one metal point—multiple points are much better—in as perfect connection with the earth as possible, preferably by several paths, raised above all stone, wood, and other non-conducting portions of the building. These points should be preferably over or quite close to the chimneys, unless wire cages are provided specially for them. Secondly, connecting all pipes, grates, bell wires and other masses of metal in the house to the conductors, preferably by means of soldered connections; when this cannot be managed, as with light and telephone leads, then by providing a small air space across which the discharge may jump harmlessly. Thirdly, by securing a good earth. When a house is built on rock, or on a thin stratum of soil over rock, or on chalk, this point requires special attention and study. Where gas and water pipes exist, they should be joined to the conductors both above and below ground, and gas and water meters should be bridged by soldered No. 5 wire. Even when water pipes exist Dr. Lodge considers it better to provide a separate earth for the conductor, also attaching it to the pipes, but this is a refinement I have not myself adopted when good water mains, always full, and jointed with lead, have been at hand.

These are the three important points to keep in view in designing protective systems for buildings, and the architect or engineer should see personally that his design is carried out. If such precautions were general, we should hear less of mysterious fires than we do.

One thing has been brought out over and over again in connection with lightning conductors. Ordinary workmen are quite untrustworthy, and require constant supervision.

In conclusion, I am able to show you some effects of a recent lightning storm, which emphasise the necessity of having the highest point of any structure earthed. Last month a telephone wire erected on the tops of poles between Murtle and Cults, in Aberdeenshire, was struck. The wire was out of use, and was insulated at both ends, so that the lightning found no vent at the extremities. It accordingly struck through the solid porcelain insulators to the iron bolts supporting them, and jumped thence to the earth wire, which was stapled up the poles to within an inch or two of the bolts. It shattered the insulators on the 1st, 2nd, 7th, 15th and 35th poles, counting from Murtle. At three of the poles the wire, No. 18 B.W.G. silicium bronze, was fused, and at the foot of one pole the earth was distributed and the grass burnt. Three of the insulators with fragments are on the table before you; the others were reduced entirely to small pieces, many of which could not be found. On one of those before you a metallic deposit from the fused wire is distinctly visible. Had each pole carried an earthed point raised above the topmost wire, the discharge would, almost to a certainty, have neglected the path of far higher resistance through the wire and porcelain, and all damage would have been avoided.

This is a weak point in our telegraphic practice, common to post office, railway, and telephone companies, and one which I have raised my voice against for a good many years past. In the figure, A shows

the ordinary method of terminating the earth wire, which leaves the topmast line unprotected, and B the method I have adopted with the object of shielding it.

In house practice the analogy to the short earth wire is a system of gas or water pipes, bell or other wires, extending up to, say, the attics, with a non-conducting structure of plaster, wood, and slates intervening between the highest point touched by the metal and the air of the house. This non-conducting stratum absolutely does not exist when lightning is in question, and in the event of a discharge occurring between the metal in the house and the clouds above, would be shattered and scattered just as you see these insulators have been. It is a curious question what the precise nature of the force is that splits porcelain in the manner shown. The destruction of trees and telegraph poles by lightning has been attributed to the sudden generation of steam in the pores of the wood, due to the heat of the discharge or to expansion by the heat of the air which the wood contains; but in porcelain there is neither moisture nor air; yet, as you see, when it chances to intervene in the path of the least resistance, that does not prevent it from being split up and utterly destroyed.

**Lighting at Southampton.**—Messrs. Crompton & Co. are erecting the central station of the Southampton Electric Light and Power Company, Limited. Current will be charged for by meter.

## UPON THE PERFORMANCE OF SIMILAR SYSTEMS OF DIFFERENT DIMENSIONS.

By W. MOON.

IN studying the different effects produced by similar systems of different dimensions, it is sometimes convenient to speak of the system being increased in all its dimensions  $D$  times and producing an effect of  $D^n$  times.

Thus the gravitational force between two bodies is proportional to the product of their masses directly, and to the square of their distance apart inversely, and, therefore, if the two bodies and their distance apart is uniformly increased  $D$  times, then the force between them will be increased

$$\frac{D^3 \times D^3}{D^2} = D^4 \text{ times.}$$

In a similar manner take two magnets that are small as compared with their distance apart, then the deflective force of the one upon the other will be proportional to their masses directly and inversely as the cube of their distance apart, and, therefore, with several such systems the deflective force exerted by each is proportional to

$$\frac{D^3 \times D^3}{D^3} = D^3,$$

provided, of course, that all the systems have the same magnetic intensity.

The force between two electrically charged bodies  $= \frac{q \times q_1}{d^2}$ , so that in similar systems of different dimensions charged to the same surface density the force is proportional to

$$\frac{D^2 \times D^2}{D^2} = D^2.$$

The distribution of the charge over the bodies would remain uniform only when the surface density was constant, whatever the dimensions. That is when the potential of the charge varied as the dimensions.

The gravitational force of a body at a point when the body together with the distance of the point are uniformly increased  $D$  times is proportional to  $D$ .

The intensity of field produced by magnets of different sizes, but of the same intensity of magnetism, is constant at similar points whose distances from the magnets is proportional to their dimensions.

Similarly the electric force of charged bodies upon points at distances proportional to the dimensions of the body is the same when the bodies are charged to the same surface density.

The kinetic energy generated by gravity in forming a body, or system of bodies, by bringing up the particles of matter from infinite distance would be proportional to  $D^5$ .

The potential energy of bodies charged to constant surface density is proportional to  $D^3$ , that is, it is equal to half the product of the potential and the charge  $= \frac{D \times D^2}{2}$ .

The energy expended in magnetising a permanent magnet is also proportional to  $D^3$ .

The difference between these three effects is interesting.

While kinetic energy is generated in bringing together the particles of a body by gravity, on the other hand, potential energy is created in giving a body a static charge of electricity, and in the case of a permanent magnet energy is expended in its magnetisation which is not again recoverable. In the last case the energy expended is proportional to  $\frac{I^2}{2} K$  where "I" is

the intensity of magnetisation and "K" the coefficient of susceptibility.

However, in the case of a temporary magnet the energy is recoverable and is proportional to

$$\frac{1}{4} \frac{H^2}{\pi} + \frac{1}{2} K = \frac{1}{8} \frac{1}{\pi} \text{ H.B.}$$

per unit of mass.

Although the size of the field produced by a magnet is proportional to the magnet's size or  $D^3$ , yet the portative force is proportional only to the area or  $D^2$ . This is natural since the strength of materials is proportional also to  $D^2$ , and, like the strength of magnetism, is limited also by a coefficient.

The strain of torsion that any material will bear is proportional to  $D^2$ , or to the area when the leverage increases as  $D$ .

Therefore it follows, that with either belting or shafting the power transmitted with constant linear velocity is proportional to  $D^3$  or to mass<sup>3</sup> if the length of the shafting increases as its dimensions.

In a similar manner power can only be transmitted by a current of electricity in proportion to the area of the conductor when the fall of potential per unit length is the same and the current is proportional to the sectional area of the conductor. But when the heat generated by the current is taken into consideration, the transmission of power by electricity is at a disadvantage as compared with other means, since for a conductor heated to constant temperature the power transmitted is proportional only to  $D^3$  when the fall of potential per unit of length is constant, and it is necessary to make the fall of potential per-unit-length equal to  $D^{\frac{1}{2}}$  before the power transmitted is proportional to  $D^2$ .

If the amount of heating of the coils of electro-magnets, whose cores are similar in shape but of different sizes, is the same, then for the same induction through the cores the amount of copper upon the cores is proportional only to  $D^2$ , while, of course, the weight of the cores is proportional to  $D^3$ . The rate of expenditure of energy in the coil is also proportional to  $D^2$ , that is to the surface.

If, however, the depth of the coils upon the cores is proportional to  $D$ , instead of being the same depth upon the different cores, then the rate of expenditure of energy in the different coils would be proportional only to  $D$ . Of course the former of these methods should be used if it is desired to make the amount of copper used a minimum. But if it is required to have the resistance of the coil or the rate of expenditure of energy therein a minimum, then the latter method of having the amount of copper proportionate to the iron should be used.

If both the conductor and the iron of an armature of a dynamo vary uniformly as the dimensions; then when the conductor in each case has the same linear velocity, the E.M.F. generated will be proportional to

$D$ , and the resistance of the conductor to  $\frac{1}{D}$  and if the

external resistance also varies as  $\frac{1}{D}$ , the current generated would be proportional to  $D^2$  and the heat given off in the armature and the work performed would be proportional to  $D^3$ . But the radiating surface of the armature is proportional only to  $D^2$ , and it is not therefore possible for a dynamo to have an output proportional to its mass if its heating is considered.

Again, since it is generally necessary to have the different dynamos give the same E.M.F., then the resistance in each case will be proportional to  $\frac{1}{D^3}$  and if

now the current is made proportional to  $D^{\frac{1}{2}}$  that is to (sectional area of conductor)<sup>3</sup> then the heating of the armature will be proportional to  $D^2$  or to the radiating surface, while the output would be proportional to  $D^{\frac{1}{2}}$ .

The output of dynamos, then, as a general rule will be proportional to  $D^{\frac{1}{2}}$ . And since the dynamo and electro-motor are reversible it follows that the work an electro-motor will perform is also proportional to  $D^{\frac{1}{2}}$ .

In the alternating dynamo the power required to maintain the magnetism of the field magnets would of course be the same power of the dimensions as in the direct dynamo. If the amount of iron

and copper on the armature coils both increased as  $D^3$  while the linear velocity of the machine was constant; then the E.M.F. would be proportional to the area of the armature coils to the angular velocity, and to the number of turns on the

armature coils =  $\frac{D^2}{D} = D$  if the number of turns is

constant, or =  $\frac{D^2}{D \times D} = 1$  if the length of wire on

the armature coils is constant. Now, if the current in the first case is regulated to  $D^{\frac{1}{2}}$ , or in the second case to  $D^{\frac{1}{2}}$ , then in each case the rate of heating of the armature coils would be proportional to  $D^2$ , and the output of the machine to  $D^{\frac{1}{2}}$ .

Of course the size of a dynamo of a particular type and having a constant electromotive force and magnetic induction is limited by the fact that the conductors of the armature ultimately become as few as the bars of the commutator. Again, for electric lighting purposes the time of an alternation of current must not be greater than a certain amount, for this reason large alternating dynamos are constructed of a number of small coils instead of a few large ones. If it were possible to give large alternating dynamos the same angular velocity as to smaller ones, it would not of course be necessary to thus multiply the number of coils, but this is mechanically impossible since the centrifugal force would then be proportional to  $D^4$ , while the strength of materials resisting this force would be only proportional to  $D^2$ .

It is interesting to compare the performance of dynamos with that of the steam engine.

Thus suppose a boiler and its steam engine to be uniformly increased in all their dimensions whilst all the linear velocities are kept constant. As the draft is of a constant velocity the amount of fuel consumed in the furnace is proportional to the area of the grate, that is to  $D^2$ , and therefore the rate at which steam is generated is proportional also to  $D^2$ . The steam being at constant pressure, the thickness of the boiler plate and the strain upon it would be proportional to  $D$ , since the strain would be proportional to the circumference of the boiler. In like manner the thickness of the pipes and of the cylinder of the engine would vary as  $D$ , and be in proportion to the strain upon them. And since the pressure upon the piston rod of the engine is proportional to its area or to  $D^2$ , therefore the strain upon the piston, its connecting rods and shafting, belting, &c., would be proportional to their strength. Now, the piston having constant linear velocity the rate of performing work would be proportional to  $D^2$  or (mass)<sup>3</sup> or (size)<sup>3</sup>.

If, however, the linear velocity could be made proportional to  $D$ , that is, if the angular velocity and the time of a period of the engine is constant, the work the engine would perform would be proportional to  $D^3$ .

But just as the pressure of the steam is limited by the strength of the material of the boiler, so the linear velocity of the piston is ultimately limited by the velocity of the steam, so that it is only within very narrow limits that the power of a steam engine can be made proportional to its mass.

Also, as with the dynamo, so with the steam engine, the centrifugal force and the strain due to change of momentum with constant linear velocity is proportional,  $D^2$ , that is proportional to the strength of the materials to resist the strain. But with constant angular velocity, these forces would be proportional to  $D^4$ .

The capacity of similar boilers of different sizes is proportional to  $D^3$ , while the rate at which the fuel is consumed is proportional to  $D^2$ , therefore, the time of getting up steam is proportional to  $D$ . Also, since the mass of the moving parts of a steam engine is proportional to  $D^3$ , while the accelerative force of the pressure of the steam upon the piston is proportional to  $D^2$ , therefore, the time of starting the engine is proportional to  $D$ . The same, of course, applies to the time of starting a dynamo or any motor.

In similar electro-magnets of different sizes, the time of acquiring its magnetism, or its time constant, is pro-

portional to its dimensions, since its electro-magnetic inertia is proportionate to  $D^3$ , while the force accelerating the magnetism of the electro-magnet is proportional to  $D^2$ .

### THE TELEPHONE IN AMERICA.

THE development of telephonic enterprise in the United States presents many interesting features, and not the least worthy of consideration is the important position in business and domestic relations occupied by this method of communication. The promptitude with which our American cousins grasped the full meaning of the advantages and possibilities presented by the telephone, and the rapid and enormous extension of telephonic systems throughout the States, stand out in strong contrast with the slow and hesitating procedure of European countries. The electric telegraph is credited with having completely changed the methods of conducting business formerly in vogue; the telephone is responsible for a no less thorough revolution in the mode of intercourse—social, domestic, and commercial, as conducted in towns and cities.

The history of the telephone in America is practically the same as that of the American Bell Telephone Company, of Boston, and a brief account of the operations of this association may be of interest to those of our readers who have not made a special study of the matter.

The telephone was brought into a practical shape by Graham Bell in 1876, and the original patent, and all subsequent ones, both as regards the telephone and the microphone, were acquired by the American Bell Telephone Company, who thus became almost the exclusive possessors of all telephonic and microphonic appliances and installations in America.

Up to the year 1887, the company worked its patents by leasing the right of using the telephone to various associations, under certain conditions, and over defined areas. These companies paid an annual tariff of \$20 per instrument (including receiver and transmitter) hired, in addition to a charge of 25 per cent. of their receipts for the use of conduits.

The earlier concessions granted to the working companies were limited to a period of five years, and were then renewed only on new conditions. The concessionaire companies were obliged to place in the hands of the Bell Telephone Company 25 per cent. of their share capital, and at the same time were granted a reduction of 40 per cent. on the annual charge for hire of instruments. The working companies founded under these conditions have entered the third renewal of contract, so that the Bell Telephone Company is at present owner of more than half of the capital invested in telephonic enterprise in the United States.

In 1887 the Bell Company took another step in the direction of securing monopoly, by founding the American Telegraph and Telephone Company (the Long Distance Telephone Company), which undertook, with the capital of the parent association, the establishment and working of telephone lines connecting the largest towns to one another. The present system of this company embraces all the important towns from Buffalo to Washington, and the lines are being extended westward to Chicago, and in the south-west between Philadelphia and the Pennsylvania coal and oil districts.

The original patent acquired by the Bell Company expires in 1893, and in order to make competition as difficult as possible, the company has bought up all patents which are considered likely to be of practical utility. The company has also become the principal shareholder in the Electrical Subway Company of New York, and since new companies encounter great difficulty in obtaining the necessary authorisations for laying down their conduits, competition in this direction is not to be much dreaded. We may here mention that the annual charge for the use of these conduits is

fixed at \$850 per mile for a telephone cable containing 50 double conductors.

The Bell Telephone Company, in its report for the year ending December, 1888, gave the number of offices under its control as 742, in addition to 452 branch offices, the length of lines as 170,471 miles, of which 17,038 miles are underground, the number of instruments leased out as 411,511, and the number of subscribers 171,454 (now considerably over 200,000).

The overhead lines in America, whether for electric lighting, telegraphy, or telephony, generally leave much to be desired with regard to construction and maintenance. The lines of the Long Distance Telephone Company set, however, a good example in these respects, their wires being the only ones which withstood the terrible snowstorm of March 12th, 1888. Their lines have a total length of 1,491 miles, with 39,776 miles of conductors. The wires are of drawn copper 3 mm. in diameter; the posts average 40 to the mile. Among the more important lines are those between Buffalo and Rochester, 69 miles; Buffalo and Syracuse, 99 miles; Buffalo and New York, 497 miles; New York and Boston, 253 miles.

As an example of the insulation of these lines we learn that tests taken on the New York and Boston line, 253 miles in length and having 120 conductors, gave an average insulation resistance of 208 megohms per mile of conductor.

### ON MAGNETIC CIRCUITS.

By H. E. J. G. DU BOIS.\*

A CONSIDERABLE extension of our knowledge of magnetic induction has lately taken place. This, like many other additions to the realm of science, was chiefly called for in order to meet the wants of designers of electric machinery; and it has accordingly been arrived at in an essentially practical way. The aim of this preliminary communication is to show how physical science may draw advantage from some of these results, and may obtain them by unobjectionable purely physical methods. In doing so I shall not so much use the conception of lines of force, but shall rather start from the consideration of magnetisation. For it is the latter quantity, which for experimental reasons (*Phil. Mag.* [5] xxix. p. 303, 1890) I believe must be taken as the fundamental one from the physical standpoint, much more so than induction, to which such importance has lately been attached.

The idea of an analogy (even when only in mathematical treatment) of magnetic systems with other systems of fluxes (hydrokinetic, thermal, electric) dates back as far as Euler. Faraday (and following him Maxwell) and Sir W. Thomson then each developed it in his own way. It has been worked out and practically applied, however, during the last decennium.

Bosanquet (1883), Rowland (1884), W. v. Siemens (1884), Gisbert Kapp (1885), especially consider the analogy with the flow of electricity, and accordingly apply Ohm's law to magnetic circuits. As, however, this law essentially implies the resistance being constant, independent of the current flowing, the above extension of its most characteristic meaning can hardly be conceded from the physical point of view; nothing is thereby meant to be said against certain practical advantages gained by introducing an (essentially variable) magnetic resistance. Quite lately, again, Pisati (1890) has laid much stress upon the analogy with thermal circuits, and accordingly has applied Fourier's law to certain magnetic systems. This appears perhaps less objectionable in so far as thermal conductivity is not necessarily a constant as its electric analogue is, though Fourier originally introduced the former as such. But

\* Translation communicated by the Author to the *Phil. Mag.* for October, 1898, being the abstract of a paper read before the Physik. Gesellschaft, Berlin, June 27th, 1890.

even then it depends upon temperature, not upon its space-variation or upon the flow of heat: the analogy is therefore in no case a complete one, magnetic conductivity being of course independent of magnetic potential.

No physical objection, however, appears to exist to the totally different treatment the question received at the hands of J. and E. Hopkinson (1886): they started from two safely established mathematical propositions, and only made some auxiliary assumptions in order to simplify the (approximate) calculations. In this way they so arrived at their graphic construction, now used to a certain extent in machine design, and which will be reverted to below.

Poisson's old theory of magnetic induction, extended by Neumann and Sir W. Thomson, as laid down *e.g.* in Maxwell's treatise, is known to rest on the fundamental assumption of constant susceptibility; it therefore applies to all substances except "ferromagnetics" (iron, cobalt, nickel, magnetite, and any substance which may yet be found to behave similarly). Kirchhoff then introduced a new theory (in 1853) by making the more general assumption that magnetisation is a function (capable of experimental determination) of the total magnetic intensity. Besides the important solutions of certain particular cases (ellipsoid, closed ring), he restricted himself to giving a few integral equations in the place of Poisson's. However, these were of but little practical use, and are hardly more so now that Duhem has lately taken up the analytical problem anew.

A more geometrical treatment of the new theory showed the distributions of the vectors concerned to be as follows:—(a) magnetic intensity: lamellar; (b) magnetisation: complex-lamellar; (c) induction: solenoidal; (d) also the three vectors are easily seen to have the same direction at every point. The proof and further discussion of these propositions cannot be given here. It may be remarked that homogeneous, isotropic ferromagnetic substance is assumed, through which no electric currents are supposed to flow; neither is hysteresis taken into account.

The simple type of a circuit not completely closed is a thin ring containing a radial air gap and subjected to a uniform tangential magnetising force. This particular case, a solution of which has to my knowledge never been attempted, is reducible to the known case of an ellipsoid of revolution. In fact, it is only necessary that the "self-demagnetising factor" be capable of calculation; *i.e.*, the number into which the magnetisation has to be multiplied in order to obtain the intensity of the self-demagnetising effect. Let this numerical factor be, as usual, denoted by  $N$ ; for sufficiently long ovoids (prolate ellipsoids of revolution) of axial ratio,  $m$ , it is found by the well-known equation

$$N = \frac{4\pi}{m^2} (\log_e 2m - 1).$$

Now let the gap of our ring have the angular value  $\alpha$ ; *i.e.*, an arbitrary concentric circle in it being considered, the  $\alpha/360$  part of this will lie in air, the  $(360 - \alpha)/360$  part in the ferromagnetic substance. A consideration of the line integral of the self-demagnetising intensity, which must vanish along any such closed circular line of integration, leads as a first approximation to the result that

$$N = \frac{4\pi\alpha}{360 - \alpha} [\text{approx. } \div 0.35\alpha].$$

The proof cannot well be given without a diagram. Both particular cases are now comparable in every respect, as the following short table shows:—

Ovoid.	Factor.	Ring.
$m$ .	$N$ .	$\alpha$
20	0.048	2.41
30	0.032	1.22
40	0.026	.76
50	0.018	.52
100	0.0054	.15
$\infty$	0	0

Now Lord Rayleigh has given a graphic construction for ovoids, which Ewing expresses in the following words:—From the ordinary curve of magnetisation for infinitely long ovoids, that corresponding to a given finite one may be obtained by shearing the diagram parallel to the axis of abscissæ through an angle, which is simply determined by  $N$ , therefore also by the given ratio of axes. By the above the curve for closed rings may now, in the same way, be sheared into a diagram for a ring with a given angular gap.

The analogy of this process with the Hopkinsons's well-known graphic method is obvious, though at first essential differences appear to exist; *e.g.*, the quantities used for co-ordinates are not the same in both cases. However, a comparison in detail finally leads to the identification of both constructions, so that in any given particular case the curves would exactly overlap, supposing the co-ordinates to be measured to proper scales. Our problem, a solution of which was first necessitated and afterwards approximately given by machine practice, has therefore now been solved to the same order of approximation by physical methods.

The degree of this approximation, the allowable limits for thickness of ring and width of air gap, the amount of "leaking" of lines of force, &c., can only be determined by experiment on as large a scale as possible.

## STREET RAILWAY MEN IN CONVENTION.

### *Cross-examining Electricians. Revelations.*

UNDER the presidency of Mr. J. N. Partridge, the Street Railway Association of the State of New York, held its eighth annual meeting on the 16th ult., at Rochester. The President, in his address, dwelt upon the marked progress that had been made since the last meeting by the substitution of mechanical and electrical devices for the propulsion of street cars in the place of horses. This address, whilst setting forth some of the advantages of electric traction contained nothing of special interest, and it was followed by a paper "On an Electric Street Railway Motor," read by Mr. J. W. McNamara. This paper, the only one presented to the meeting, was very short, concise and to the point; it referred to the conversion of a horse car line at Albany into an electric one, by the Thomson-Houston Company. The contract was given out on the last day of November, 1889, and on May 1st, 1890, all the horses on that line were withdrawn. None of the drivers had had any training until the evening of April 27th, 1890, yet they were able to begin running schedule trips with three cars the next day. Four months' experience has taught the author that the electric motor is efficient and reliable, but he has yet to learn that it will ascend an 8 per cent. grade at the rate of 5 miles per hour in winter as it did in summer. The question as to whether the electric motor is as economical as the horse cannot yet be answered, and need not be answered—so says the author in concluding his address.

The "discussion" which followed was remarkable, for several reasons: in the first place hardly any reference was made to the paper read; secondly, the speakers, mostly representatives of contractors, referred to the advantages of their respective "systems," somewhat depreciating those of rival concerns; and, thirdly, for the cross-examination which certain electrical experts had to undergo, which revealed some interesting facts.

Mr. Frank Rogers, representing the Short Electric Railway Company, of Cleveland, stated that the "series" system has been abandoned by his company, and that they used now the parallel system, like Thomson-Houston and Sprague. Questioned by several gentlemen as to the reasons why the "series" system has been abandoned by its own inventors and former advocates, Mr. Rogers explained that it could only be worked successfully with two or three cars, but with

more than five on the line it was a failure. The trouble was, that it was difficult to manufacture a constant current generator that can be operated with little attention. "The generator fluctuates, so that it does not take care of the current." In the parallel system the electromotive force is constant. In the series system the current should be, but is not, and for that reason it is not adapted for a large number of cars. The construction of the conductor was too complicated, a switch being used in it. Prof. Short, the originator of the "series" system, had studied the question very carefully, and has spent a great deal of money in trying to work the system up and make it a success, and has also experimented largely in underground work before the new company was organised; but since then the parallel system has been adopted.

Mr. Rogers prefers the single overhead wire and rail return; it is not so complicated, and in a large city where there is one line crossing a number of tracks, it lessens the number of wires overhead. At Cincinnati they were obliged to put in the parallel double overhead wire on account of the telephones there, and the street railway managers being largely interested in the telephone companies. Many other questions of less importance were addressed to Mr. Rogers and satisfactorily answered, when Mr. E. E. Higgins, of the Sprague Company, which is now part of the Edison General Electric Company, was called upon to give his version on the subject.

Mr. Higgins claimed that the principal things brought out by Mr. Sprague, and copied ever since, were the placing of the motors underneath the cars, and attaching them to the axles on one side, and to a spring support on the other. Then the control of both motors of the car from either platform was another important point. The method of winding the Sprague motor field, says Mr. Higgins, is entirely different from all others. They are wound in three sections each; the control of speed is effected by different combinations of these coils without the use of wasteful resistances. The consequence is that the cost of coal per car is less than with any other system. Mr. Higgins does not seem to be aware that all these points, which render the Sprague system so superior, were invented and applied by Mr. A. Reckenzaun long before, as can be readily seen by Mr. Reckenzaun's patent specifications, 1882 to 1885, as well as by numerous papers read, and articles in scientific journals. The claim to the conception of the under running trolley, Mr. Higgins believes, is disputed, and presumes that it is one of those early contrivances which may have been brought out by others at the same time. It has been adopted everywhere, and is the only true way of getting at the root of the matter. Since August 1st, Mr. Edison had been devoting his entire attention to some changes in the motor. They referred merely to mechanical details. The fields of the motor are now spread slightly, so as to allow of more wire on the cores. The gears have been widened, but the most important advance which has recently been made in electrical railway work is the adoption of the new style of winding the armatures. The old armatures were wound in accordance with what is called the Siemens method; the wires at the ends of the armature are in a bunch, crossing and recrossing each other, and not being firmly fastened in place, there is necessarily some chance for the play of wires, and this results in the armatures frequently burning out. The first effect of this method is that there may be a maximum pressure wire touching a zero pressure wire, and the slight motion between these two will cause the insulation to become abraded, and a short circuit follows. In the new armatures the coils are wound separately, and there is no bunching of wires at the ends. No definite description of the winding is given; but if the "drum" armature is adhered to, we presume the ends will be arranged on a plan similar to that devised by Mr. Crompton for his dynamos.

Mr. Norman McCarty, of the Thomson-Houston Company, mentioned that his firm had long recognised the fact that the electrical railway apparatus is not so much an electrical as a mechanical problem. They use plain

series-wound field magnets, and have made up their minds that it is a good deal better to spend a little more for coal, and avoid wear and tear. This company uses the much-abused rheostat, which has the advantage that the car can be started without a jar. Regarding line construction, the Thomson-Houston Company is not limited by any patent, the method of construction varying with the conditions of the circuit. There is a patent on a system by which the line is fed at regular intervals; there is no patent on the ordinary system used.

Interrogated by Mr. Richardson, Mr. McCarty stated that he could not explain the superiority of the Thomson-Houston system over the Sprague system without criticising the latter. The Thomson-Houston cars and trucks were heavier, the motors heavier and stronger built, the gears were wider, and electrical complications were eliminated. He did not care about electrical theories so much as mechanical perfection, and that was the secret of his company's success.

Mr. Richardson asked purely for information, as he represented several tramway companies which were contemplating the purchase of electrical apparatus, and had not purchased a thing yet. He called attention to the fact that a leading Boston newspaper sent out letters asking for information from all cities in which electric railways were operated, enquiring what systems they used, whether there had been any loss of life in connection with the wires, whether there was any objection to the overhead system on the part of the public, and what had been the effect on the street railway service of the particular locality. Answers had been published, so far as received, from 64 different places, and all but four of them were favourable to electricity. Nashville, Tenn., was the only place where there was any loss of life reported, and the answer from that place was very amusing. There had been a wire broken in the city, causing the death of a horse, and a negro woman caught up the wire and threw it over, and it gave her a shock that was very funny in its effects, but did her no injury. It killed the horse, but it did not kill the woman, going to show that it is easier to kill a horse than it is to kill a human being, especially a "nigger."

Another objection came from Newport, R.I., where the "upper ten" were objecting to anything which should popularise riding.

Mr. F. R. Chinnock, in referring to complaints on the part of telephone companies, said that the simple way to prevent induction caused by electric railway wires is to provide a return metallic circuit; but suggests that the telephone people should go to this expense.

## BRITISH ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.—LEEDS, 1890.

### SIR WILLIAM THOMSON'S NEW ELECTRICITY METER.

(Read before Section G, September 8th, 1890.)

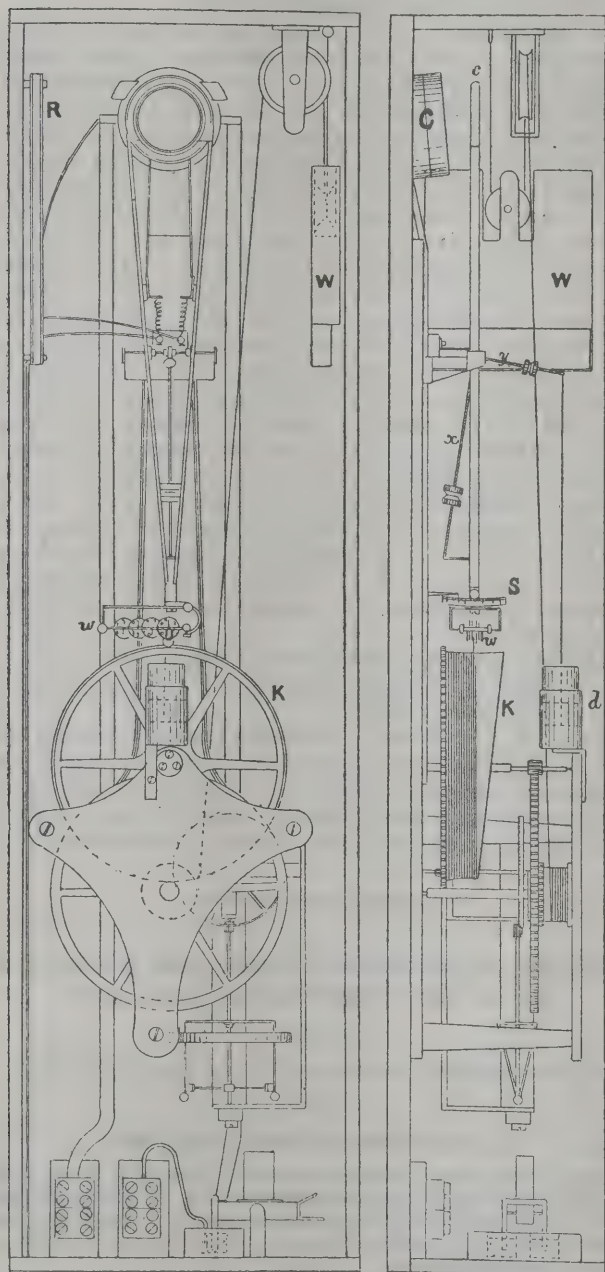

This instrument forms at once an indicator, by which the strength of current passing at any given instant can be read off on a scale, and a supply meter, by which the amount of current that has passed through the meter during any given time is recorded on a train of counting wheels.

The indicator consists of a light aluminium frame, free to turn about a horizontal axis, having at its top end a coil of fine copper wire, *c*, and at its lower extremity a train of counting wheels, *w*. The frame is supported on knife edges, and a current is conducted into and out of the fine wire coil by two spirals of fine copper wire, *n*. The resistance of this coil is about 30 ohms and it is joined in series with an anti-inductive platinoid resistance, *R*, of 970 ohms. When the meter is in action a small current is kept passing through this circuit. The whole current to be measured is conducted through a fixed coil, *c*, of copper ribbon, which is placed with its plane parallel to the plane of the fine wire coil when the latter is in its zero position. A scale, *s*, divided to give readings in amperes is attached to the indicator, on which the strength of current passing through the fixed coil can be read off by means of an index fixed to the case of the instrument.

The recording apparatus consists of the train of counting

wheels, w, mentioned above and a revolving cam, x, driven by clock-work which is kept in motion by a weight, w. The cam is kept revolving at a uniform rate, and, when a current is passing through the instrument, comes in contact at each revolution with a trailing wheel attached to the counting train which it causes to turn round; and so makes a record.

The action of the meter may be shortly stated as follows:—When no current is passing the indicator stands at 0 on the scale, s, the movable coil is about 1 millimetre from the fixed one, and the trailing wheel of the counter train is quite clear of the cam, so that no record can possibly be made. When a current is passing through the fixed coil, the top end of the indicator is repelled outwards, and the counting train of wheels is brought inwards towards the cam to a position depending upon the strength of current which can be read off on the scale. In this position, at the proper time of the revolution, the trailing wheel is lifted by the cam, and runs over a shorter or longer path in proportion to the strength of current passing. Thus, if the current passing through the fixed coil be 5 ampères the counting wheels might record 20 for every revolution of the cam, whereas were the current 10 ampères the trailing wheel would roll over twice as long a path and the record would be 40.

Two screwed rods are so attached to the indicator that one, x, is vertical, and the other, y, is horizontal when the beam is in its zero position. These rods are provided with adjustable nuts—those on the vertical being to adjust the sensibility of the instrument, while those on the horizontal rod are for the adjustment of the zero. By means of the former the constant of the meter can be quickly varied if found convenient. Thus a meter which is suitable for measurement from 1 to 20 lamps can be altered in a few minutes to suit ranges of from 1 to 50 or from 1 to 100 lamps. This adjustment can be made by an inspector without the use of any auxiliary instrument. All that has to be done is to hang on a weight of a given amount on the knife-edge stirrup at the end of the horizontal arm and raise or lower the nuts on the vertical arm till the indicator shows a given reading on its scale.

By this means also the constant of the meter can be checked at any time.

As at present arranged the driving weight needs to be wound up periodically by means of a revolving disc on the front of the case. It is intended that this should be done by the consumer, and an arrangement is made by which the current is automatically cut off from the house when the weight is allowed to run down. Precautions are also taken to prevent any fraudulent tampering with the instrument.

### ON THE VALUES OF CERTAIN STANDARD RESISTANCE COILS.

By R. T. GLAZEBROOK, F.R.S.

(Presented to Section A, September 9th.)

THE Standard B.A. units of the Association have during the year been several times compared together both by the secretary and by Mr. Fitzpatrick. Table I. gives the results of two sets of comparisons made in August, 1890. The differences between the various coils and the platinum silver standard Flat are given in the third column in bridge-wire divisions. One bridge-wire division is very nearly 00005 B.A. unit.

TABLE I.

Resistance of the B.A. Standards, August, 1890.

Coil.	Temperature.	Difference between each coil and flat in bridge-wire divisions.		Observed calculated.	Change of resistance per 1° C. in b.w.d.
		Observed Aug. 15, 1890.	From chart. 1888.		
A	17.2	27.8	33.0	— 5.2	28.6
B	17.4	30.5	30.5	— 0.0	28.8
C	17.6	22.2	23.0	— 0.8	14.2
D	17.25	61.2	63.5	— 2.3	61.7
E	17.3	79.2	79.5	— .3	60.7
F	17.3	3.2	— 9.5	12.7	5.7
G	17.5	— 22.0	— 18.0	— 4.0	5.5
H	17.4	— 17.0	— 15.0	— 2.0	5.6
August 19					
A	18.8	67.5	69.5	— 2.0	28.6
B	17.8	60.6	62.0	— 1.4	28.8
C	19.2	31.6	36.0	4.4	14.2
D	18.8	145.7	15.1	5.3	61.7
E	19.0	170.6	17.3	2.4	60.7
F	18.9	2.9	— 9.5	12.4	5.7
G	19.0	— 21.8	— 18.0	— 3.8	5.5
H	19.0	— 17.7	— 15.0	— 2.7	5.6

In the fourth column are given the corresponding differences obtained from the chart made in 1888. In the next column will be found the differences between the observed values and those given by the chart, while the sixth column gives the change in resistance for 1° C. for the various coils. It will be seen that for the first five coils the differences between observation and the chart are such as would be readily accounted for by a small error in the temperature, and we may say that there is no evidence of a change in the resistance of these coils relative to Flat. This conclusion is borne out by the results of a series of observations made in January and February by Mr. Fitzpatrick. But when we come to the three platinum silver standards, F, G, H, the results are at once seen to be quite different. Thus F would appear to have risen relatively to Flat by about 12.5 bridge-wire divisions, while G and H have fallen by 4 and 2.5 divisions respectively.

Since these are the most important standards, their temperature coefficients being all very small, it was necessary to examine their history with some care. A change in F had been noted in a postscript to the report for 1888. The general conclusions of that Report were that up to the summer of 1888 there had been no change in the value of the coils. It was shown that all the original platinum silver coils examined then—those of Messrs. Elliott, H. A. Taylor, and others, as well as those belonging to the committee—had apparently fallen in value relatively to the mean B.A. unit by about 0007 B.A.U. since 1867, but evidence was adduced to show that the fall was only apparent and was due to an error in the temperature coefficient used at that date. A single observation of Chrystal in 1876 pointed to the possibility of a change in F, but that change was not confirmed by other evidence; while so far as the platinum silver coils were concerned, the observations of Dr. Fleming in 1881, and myself in 1888, agreed closely.

Since 1888, however, changes have shown themselves.

These are evidenced by the three following tables II., III., and IV., which give the differences Flat-F, Flat-G, and Flat-H respectively,

TABLE II.—Value of Flat-F.

The three first lines in each table give the differences at the temperature shown taken from the chart drawn in 1888; the remaining lines give the differences actually observed, with the dates and temperatures. Thus, taking the various coils, it is clear that while up to May, 1888, the difference between Flat and F remained the same as shown by the chart and observations up to that date, a change took place during the low temperature observations in July, 1888, while by the time the coils were again examined in January, 1890, a further change had manifested itself. This continues up to the present date, so that now at temperature of about 15 deg. the coil F has increased in resistance relatively to Flat by about 12·7 bridge-wire divisions. This, assuming the whole change to be in F, will correspond to a rise of resistance of '00063 B.A. units, or, in other words, the temperature at which the coil is right has fallen by about 2·3°. In January, 1890, the coils were again exposed to a low temperature, and it seems probable that the changes took place when the coils were in ice.

Turning now to Table III., which gives the values of Flat-G, we see there is no evidence of change till May, 1890. The observations in July, 1888, and January and February, 1890, are quite in accordance with the chart, but in May, 1890, it is clear that G has fallen relative to Flat.

The value of the difference at a temperature of 16° is 22·1 b.w.d.

as against 18·1 given by the chart. Thus G has fallen relatively to Flat by 4 b.w.d., or '0002 B.A. units. This change was first observed after the coils had been exposed to a low temperature.

With regard to H the change first showed itself during the low temperature observations in January and February, 1890, and Table IV. indicates that the difference between Flat and H is now 17·5 divisions as against 15·5 in 1888, or in other words, that G has fallen by '0001 B.A. unit. Also since Flat-F changed in 1888, while Flat-G and Flat-H did not, we infer that the change at that date was in F, not in Flat, while since Flat-H changed in January, 1890, without a change in Flat-G, it appears that the change was in H, not in Flat; and finally, from the observations in May, 1890, which show a change in Flat-G, but none in Flat-H and Flat-F, we infer a change in G.

As to the cause of these changes, we can say but little. We hope to investigate them more completely by the aid of the coils lent by Mr. H. A. Taylor and others, and referred to in the 1888 Report; but it seems possible that they are due to strains set up in the wire by the great contractions and expansions produced by cooling and heating in the paraffin in which the coils are embedded. The coil Flat is of a different shape to the others and little or no paraffin has been used in its construction. The other coils, F, G, H, are embedded in paraffin in the usual way. On cooling down to 0°, this shrinks greatly, and it is quite conceivable that this shrinkage may have strained the coils and so caused the change. We hope to test this by having coils made free from paraffin and investigating with them the effects of repeated heating and cooling. The fall of H and G would be accounted for by a loss of insulation causing a slight leak either from the wire to the case or across the surface of the paraffin. The insulation resistance for F, G, H, was therefore tested and found in each case to be several thousand megohms, while the surface of the paraffin which had become dirty with time, was scraped, but without producing any change in the resistance. A leak, of course, would not produce the rise found in F.

Observations of the coils at 0° have always been unsatisfactory and attended with considerable difficulty. This is mainly due, I believe, to the fact that the temperature of the room in which the observations have been made has usually been above zero, and that heat is conducted into the coils by the thick copper connecting rods. It would seem possible, however, that part of the difficulty (*See* Report of the Committee for 1888, Table VII.) may have been due to real changes in the resistance arising from strains set up by the cooling.

*The Legal Ohm Standards.*

The results of observations on the legal ohm standards of the Association are given in the Report for 1886. Experiments made in these between July, 1884, and January, 1886, showed that while one coil, C.L.C. 100, had retained its value unchanged, the other, C.L.C. 101, had varied. These observations have been continued, and the results are given in the following tables, which give the value of each coil as found by direct comparison with the standard B.A. units, and its value as given by the chart in 1886.

TABLE V.—Results for C.L.C. 100.

Date.	Standard used in comparison.	Temperature.	Value.	Value on Chart.	Difference.
Feb., 1887	F	16·3	1·00009	1·00008	·00001
Nov., 1889	G	15·8	·99997	·99996	·00001
"	"	14·8	·99971	·99968	·00003
"	"	16·0	·99998	1·00000	·00002
Dec., 1889	Flat	14·4	·99962	·99959	·00003
"	"	14·8	·99969	·99968	·00001
"	"	13·2	·99925	·99924	·00001
"	"	6·2	·99744	·99735	·00009
"	"	5·7	·99729	·99720	·00009

TABLE VI.—Results for C.L.C. 101.

Date.	Standard used in comparison.	Temperature.	Value found.	Value on chart in '85, '86.	Difference.
Feb., '87	F	16·3	·99970	·99930	·00040
Nov., '89	G	15·9	·99955	·99920	·00035
"	"	15·1	·99932	·99899	·00033
"	"	16·0	·99955	·99922	·00033
Dec., '89	Flat	14·4	·99909	·99880	·00029
"	"	15·0	·99925	·99897	·00028
"	"	13·3	·99879	·99850	·00029
"	"	7·6	·99725	·99695	·00030
"	"	6·5	·99701	·99668	·00033

These tables show three facts conclusively:—(1) That up to December, 1889, no appreciable change had taken place in the relative values of C.L.C. 100—the legal ohm standard—and Flat or G; (2) that between January, 1886, and February, 1887, C.L.C. 101, which had varied previously, changed by about '0004 ohms; and (3) that the greater part of that change has remained permanent up to December, 1889. At present the difference between

C.L.C. 100 and C.L.C. 101 is about '0004; in 1886 it was about '0008. The agreement between the observations in November and December, 1889—in one set of which Flat was the standard of comparison, while in the other G was used—show that the relative change in G and Flat took place after this date.

## DISCUSSION ON THE REPORT OF THE COMMITTEE ON STANDARDS.

(Tuesday, September 9th, 1890.)

The following discussion took place on the report of the committee, and the papers by Prof. Fitzpatrick and Messrs. Glazebrook and Griffiths:—

Prof. FITZGERALD said that he did not understand whether an attempt had been made to anneal the specimen of copper that gave the very abnormal density and low conductivity, or whether annealing would alter it. He also asked where the copper came from, because it would be interesting, in connection with the committee that had been appointed to make experiments on this abnormal copper, whose thermo-electric properties were also connected with this. He would like to find out where specimens could be got.

Dr. FLEMING answered the questions of Prof. FitzGerald, stating that he had obtained the copper from Mr. Elmore.

Mr. SWINBURNE remarked that in some American books, for instance, they gave a figure something like 784 as the most recent determination. But if there was any chance of an error of 4 or 5 per cent. in that, he thought it would be important to determine it again.

Mr. FLEMING said that one question raised seemed important in connection with changes in the coils, and that was the strains taking place in the wires as they were usually wound. Paraffin expanded and contracted during heating, and he was inclined to think that it would be better to use liquid paraffin. He was sure the members of the section fully appreciated the value of the work that Mr. Glazebrook was doing in keeping a careful watch on those coils for slow changes. Those coils constituted standards for all the world, and it was most important that a watch should be kept on them to detect normal changes. It was a most unfortunate fact that the standards were made of complicated alloys. The simple metals which would be better adapted for permanent standards having very high temperature coefficients. Some experiments had been carried out in the United States on alloys. One of these alloys was compounded some time ago by Mr. Weston, and Dr. Nicholls has published a paper on the matter. The alloys consist of copper nickel and ferro-manganese, and have a negative coefficient with change of resistance with temperature. It had been found that by suitable combination of these alloys it was possible to have an alloy that did not change its temperature. Unfortunately, however, these ferro-manganese alloys were not at all likely to be used, because they changed their resistance with small currents. His acquaintance with coil G had ceased for some time, but he had some recollection that that gold and silver coil gave them some anxiety. So far as he could follow Mr. Glazebrook, however, it was the coil F (platinum-silver) that had changed so much. This seemed to point to the necessity for more careful investigation of the changes of resistance and losses with time was required. With regard to the method of testing capacity with a revolving commutator, he had made experiments some years ago with satisfactory results. The commutator was driven by an electro-motor being keyed on to the motor shaft.

Sir WM. THOMSON was glad that Dr. Fleming had called attention to the loss of negative temperature coefficient, and said that it would be interesting for the section to know that the subject was under examination in Dr. Helmholtz's laboratory. If there was no temperature variation, they might soon hope to see coils in which they would not be troubled with any temperature error.

Mr. TROTTER said that since the B.A. Committee were dealing with the resistance of copper, it might be important to determine what was meant by copper. Tempering produced a very large change, and the expression "thorough tempered" was used. But surely, if tempering did produce any change, they ought to know what was meant by "thorough tempering." It was perfectly well known that ordinary commercial copper contained a considerable amount of oxygen. The question arose, What amount of oxygen or hydrogen might be occluded in deposited copper. It was not a purely chemical question, and should be determined.

Sir WM. THOMSON remarked that the time occupied in thorough tempering was important. It might extend over hours, days or weeks, and might produce very different results.

Prof. FITZGERALD said that that fact seemed to make the difference between pure and impure metals.

Mr. GLAZEBROOK said that the numbers in Table II. gave the resistance of the same wire that had been tested there after it had been annealed. In the one column they had the resistance of hard-drawn wire, and in the other after annealing. The annealing was done by enclosing the wire in a flat copper case, packed full of asbestos and lampblack, heating it with a Bunsen burner, and leaving it for 24 to 26 hours. In every case the numbers in the table gave the results of more than one annealing. The process of annealing was repeated again and again, and the numbers gave the mean result of as perfect annealing as could be arranged for.

Sir WM. THOMSON suggested that the use of lampblack and the

consequent presence of carbon might have a very important effect on the result, and he thought it would be well to try annealing with asbestos alone.

Dr. LODGE asked whether the section were to run away with the idea that there was something the matter with the platinum-silver alloy. Mr. Glazebrook had told them that the platinum-silver coil might be all right, but coil F had changed. He would like to know whether it had changed by more than one part in 10,000.

Prof. PERRY remarked that in some observations which he had recently been making on wires, strips of the same wire, after being flattened and twisted, behaved in such a different way as regards their elasticity that they might almost be thought to be made of different material.

Lord RAYLEIGH, in connection with the impurities of copper, mentioned some experience he had gained during last summer. In passing pure hydrogen over copper wires at a red heat, he found that the gas reeked of sulphuretted hydrogen. It was impossible to get copper that did not give off sulphur. When the wires were taken out after heating, they were absolutely brittle, suggesting the idea that the removal of the sulphur had been fatal to their mechanical properties.

Mr. SEARLE having described the methods he had adopted for rotating the commutator,

Mr. GLAZEBROOK replied to the questions and suggestions that had been made. With regard to what had been said as to annealing, he was afraid that in endeavouring to be brief, he had not been quite just to the very great care Mr. Fitzpatrick had taken on this point. There was a great feeling among copper manufacturers that a small amount of oxide was necessary to give density to copper wire, and there was a certain amount of oxide in all copper. The original reason why it was annealed in charcoal was to get rid of that oxide, and he fancied that in almost all cases the wire did turn out brittle. At the same time it came out with a very much reduced resistance. In Mr. Fitzpatrick's method of preparing the copper, the hydrogen was passed over the copper at a red heat for a considerable number of hours. Mr. Fitzpatrick had a specimen of copper prepared by chemical means, the results of observations on which he had hoped to have had there that day, had not the breaking of a tube (obtainable only in Germany) postponed the reduction and purification of the copper until another could be got. But he fancied the copper did become distinctly brittle, and lose its density when the sulphur was got rid of. As to Mr. Taylor's remarks about Matthiessen's knowledge of the temperature coefficient, he had his formula there, and he thought the number was obtained by ranging from 16 to 100. He had not been able to find any observations of Matthiessen lower than 16; if Mr. Taylor had numbers nearer 0, they would be extremely valuable to the report. Dr. Fleming had referred to the point he (Mr. Glazebrook) raised as to the effects of mechanical strain. It would be in the memory of the section that in the last clause of the report he asked for further resistance coils. It was his intention to wind these entirely without paraffin. As to the loss with negative temperature coefficient, they had been in communication with the Helmholtz laboratory, and they hoped to have specimens of wires before long. With regard to the platinum silver alloy, his impression was that there had been no change in the alloy, but that a mechanical change had been produced by strain, and he hoped that any electricians who had old coils of the Association would lend them to him again that he might compare them, and see if there had been any change. The amount of change in F was a rise of

+ '0007 B.A. unit.  
G — '0002 do.  
H — '0001 do.

He thought Prof. Perry's remarks entirely bore out his experiments. Mr. Searle said he had only taken a subsidiary part in the matter, but he made the commutator, and made it work, and that was of great importance.

The PRESIDENT (Dr. Glaisher) congratulated Mr. Glazebrook on the satisfactory nature of the report.

## ON THE ELECTROSTATIC FORCE BETWEEN CONDUCTORS CONVEYING STEADY OR TRANSIENT CURRENTS.

By Dr. OLIVER LODGE.

(Presented to the A Section, September 9th, 1890.)

At the last meeting of the Physical Society this session, Mr. Boys described some attempts he had made to detect mechanical force between a pair of Hertz resonators delicately suspended and immersed in a region of electromagnetic waves.

The attempt, so far, had not been successful; but Mr. Boys, by attending to the energy manifested by Mr. Gregory's method, and by another method of his own, showed good reason why the force, if any, was just too small to be observed even with his extremely delicate appliances, and conjectured that a moderate increase in sensitiveness would be necessary in order to detect the effect.

Every one must have full confidence that if any such mechanical effect exists, Mr. Boys will show it us before long; but, in common with Prof. Fitzgerald, I feel provisionally and tentatively doubtful whether any mechanical effect really exists between electric pulses travelling along wires with the velocity of light. In a wire subject to electric stationary waves there are obvious

electrostatic pulses at either end and electrokinetic pulses in the middle: but Mr. Boys had allowed for all that, and arranged that the opposing effects of ends and middle should conspire to assist each other in causing rotation. What I felt doubtful about was, whether even in infinite wires, wherein all complication by reflection and stationary waves was avoided, a pair of pulses travelling side by side, like a pair of humps (or a hump and a hollow) on a pair of parallel cords, would exert any force on each other. It is known that two charged bodies flying side by side with the velocity of light will exert no such effect (Mr. Heaviside has shown that this is equivalent to saying that two elements in the same wave-front exert no mechanical force on each other); but whether the same thing is true of two wire-conducted pulses has not, so far as I know, been examined by mathematicians.

If it should turn out that pulses at full speed have no effect, then two straight oscillators in similar phases should repel each other, by the electrostatic effect of the slackening and stationary pulses which are being reflected at the ends.

Such an action seems optically rather interesting. Maxwell predicted that a reflector or absorber would be repelled by light; though, as we know, the complication of the more vigorous molecular action of material surroundings prevented Mr. Crookes from detecting this precise effect. We know, however that it must exist; and the repulsive effects between alternating magnets and copper discs, detected by Faraday and recently made much of in an interesting manner by Prof. Elihu Thomson, are examples of this very thing. We can even say what the stress caused by full sunshine ought to be, viz., about 50 microbarads;\* that is, the weight of half a milligramme per square metre; but it has not yet been experimentally observed. If Mr. Boys finds his effect, at least if he finds it in the form I suggest, as an overbalancing static repulsion, it will represent an action between two sources of light or between two similarly illuminated bodies.

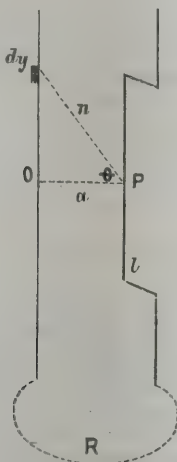

On the afternoon of the meeting of the Physical Society, by Mr. Boys's kindness, I made in a back room a hasty experiment on the pulses of a Leyden jar discharge, which was passed either in the same or in opposite directions through a pair of flexible parallel strips of aluminium foil, looked at through a microscope.

A fairly distinct effect was observed, its sign being, so far as one could tell, the sign of the electrokinetic effect; i.e., attraction between currents in the same direction, repulsion (more easily observed, because, as it was arranged, nearly four times as strong) between opposing currents. Hence it would seem, so far as this crude observation goes, that pulses in wires do exert their electrodynamic effect. I expected, however, that, by suitably arranging matters, the electrostatic effect of the pulses could be made able to overpower their electro-magnetic effect. It is perhaps rather a barbarous plan to consider the two things separately; but until some one attacks the problem in a powerful manner I have been interested in groping at it, and accordingly make this communication.

First, consider the action of currents in general on each other, and find the ratio between their electrostatic and electrokinetic forces. So far as I know, the electrostatic force between two steady currents is usually overlooked.

No advantage in generality is gained by treating two separate circuits, a movable portion arranged near a fixed portion of one and the same circuit is sufficient.

Arrange a short length,  $l$ , at a distance,  $a$ , from a long parallel conductor; with a resistance,  $R$ , intervening between  $o$  and  $P$ , the middle opposite points of each; and through the whole send a current,  $c$ , up one and down the other.

Then the difference of potential between the two points is  $Rc$ , or, with alternating currents,  $Pc$ , where  $P$  is the impedance of the wire  $R$ ; and if the capacity per unit length of the two conductors is called  $s_1$ , the linear density of charge on each is on the average  $\lambda = s_1 Rc$ ; a little more above  $o$  and a little less below it; but unless the distribution of potential differs greatly from a linear

distribution, as when  $l$  is comparable to a wave-length, the mean value will serve.

The electrostatic attraction between the two conductors is

$$F = \int_0^l \int_{-\infty}^{+\infty} \frac{\lambda dy \cdot \lambda' dy' \cdot \cos \theta}{K r^2} = \int_0^l \int_{-\frac{1}{2}\pi}^{+\frac{1}{2}\pi} \frac{\lambda dy \cdot \lambda' \cos \theta d\theta}{K a} \\ = \frac{2 \lambda \lambda' l}{K a} = \frac{2 l}{K a} (s_1 R c)^2 \quad (1)$$

Unless one of the conductors is very long there is another term, which, however, it is unnecessary to write.

The electrokinetic repulsion between the same conductors is similarly

$$F' = \int \int \frac{\mu c dy c' dy' \cos \theta}{r^2} = \frac{2 \mu l}{a} \cdot c^2 \quad (2)$$

#### Steady Currents.

Hence with steady currents the ratio of the static attraction to the magnetic repulsion is

$$\frac{F}{F'} = \frac{s_1^2 R^2}{\mu K}, \quad (3)$$

which on every possible system of units is a pure number.

To get a notion of its value, suppose the wires to be round and of radius  $\rho$ ; then

$$s_1 = K \cdot 4 \log \frac{a}{\rho};$$

so, remembering that

$$\frac{1}{\mu K} = (\text{the velocity of light})^2 = \left( \frac{30 \text{ ohms}}{\mu} \right)^2,$$

we see that the above numerical ratio is

$$\frac{F}{F'} = \left\{ \frac{\text{number of ohms in the wire } R}{120 \log \frac{a}{\rho}} \right\}^2 \quad (3')$$

Suppose, for instance, the wires were 50 diameters apart, or  $4 \log a/\rho = 18.4$ , the two forces would be equal, and just balance each other, if  $R$  was 552 ohms.

With any resistance greater than this the electrostatic force would have the advantage, and two opposite currents in the given wires would attract.

#### Alternating Currents.

If the current used is an alternating one, impedance must be inserted in (1) and (3) instead of resistance: no other change is necessary. Hence an impedance meter suggests itself. Send a current alternating with given frequency through the pair of conductors joined by the impedance to be measured, and either adjust  $s_1$  until the electrostatic and electrodynamic forces balance, or estimate the outstanding force by a torsion arrangement. Supposing a balance could be got, the impedance of the intervening conductor, for the particular frequency applied, is

$$P = \frac{1}{s_1 \cdot v} = 60 \log \frac{a^2}{\rho \rho'} \text{ ohms.}$$

#### Leyden Jar Discharge.

Next proceed to consider the transient current of a Leyden jar discharge round the same circuit.

Let a jar of capacity  $s$  charged to potential  $v_0$  be discharged round a circuit whose total resistance and inductance are  $R_0$  and  $L_0$  respectively. Then the current at any instant after the discharge has begun is

$$c = \frac{v_0}{P L_0} e^{-m t} \sin p t; \text{ where } m = \frac{R_0}{2 L_0}, \text{ and } m^2 + p^2 = \frac{1}{s L_0}.$$

The electrodynamic repulsion between the two wires previously considered, when the discharge occurs, is, therefore, applying (2), an impulse:—

$$\phi' = \frac{2 \mu l}{a} \cdot \left( \frac{v_0}{P L_0} \right)^2 \int_0^\infty e^{-2 m t} \cdot \sin^2 p t \cdot dt \\ = \frac{2 \mu l}{a} \cdot \frac{1}{2} s v_0^2 \cdot \frac{1}{R_0} \quad (4)$$

To investigate the electrostatic attraction completely we should have to take into account the sinuous distribution of potential in space over the circuit; but, unless the waves are much shorter than usual, the ultimate effect on a short length will be very little different from the effect of a uniform potential alternating sinusously in time, the difference of potential at any instant between the fixed and movable wire being

$$V = P c,$$

where  $P$  is the impedance of the intervening portion of the circuit. Hence the electrostatic impulse is, by (1),

\* Langley's recent estimate, that a square centimetre fully exposed to sunshine receives 2.84 C.G.S. thermal units per minute, is equivalent to an energy of 67 ergs per cubic metre of sunshine, or 67 microbarads. (A "barad" means an erg per cubic centimetre, or a dyne per square centimetre.)

$$\phi = \frac{2l}{\kappa a} s_1^2 P^2 \int_0^\pi c^2 dt$$

$$= \frac{2l}{\kappa a} \cdot \frac{\frac{1}{2} s v_0^2}{R_0} \cdot s_1^2 P^2. \quad (5)$$

And the ratio of the two impulses is

$$\frac{\phi}{\phi'} = \frac{s_1^2 P^2}{\mu \kappa} \quad (6)$$

Now  $P^2 = p^2 L^2 + R^2$ , where  $p^2 = \frac{1}{s L_0} - \left( \frac{R_0}{2 L_0} \right)^2$ .

So, noticing that  $R/R_0 = L/L_0$  as nearly as we please,

$$P^2 = \frac{L}{L_0} \left( \frac{L}{s} + \frac{3}{4} R_0^2 \right).$$

The second term is frequently negligible, though there is no difficulty in taking it into account if it is not; so the ratio of the impulses, at its least is

$$\frac{\phi}{\phi'} = \frac{s_1^2}{\kappa^2} \cdot \frac{L}{L_0} \cdot \frac{L/\mu}{s/\kappa}. \quad (6')$$

The first of these three numerical factors depends merely on the shape of the acting conductors and their distance apart. The second is a proper fraction which may be made as near unity as we choose. The third involves a comparison between the electro-magnetic measure of inductance of the wire included in the circuit, and the electrostatic measure of capacity of the discharged Leyden jar.

Taking as an example the same round wire conductor as before, with

$$s_1 = \frac{\kappa}{4 \log \frac{a}{\rho}} = \frac{\kappa}{18.4}, \text{ say,}$$

and considering  $\frac{L}{L_0}$  as  $\left( \frac{18.4}{20} \right)^2$  for instance, we perceive that

the two impulses will be equal and just balance each other if the length representing  $L$  on the magnetic system of units be 400 times as great as the length representing  $s$  on the electrostatic system. Any wire longer than this gives attraction the advantage; any wire shorter than this favours repulsion.

Or, with different jars discharging round a given circuit, small jars will exhibit the electrostatic impulse, big ones the electrokinetic.

Illustrating numerically still further; a length of 30 metres of No. 16 copper wire opened out into a single large loop has a self-induction of 500 "metres" or 50 micro-secohms. Using this as the wire  $R$  between the two suspended conductors, the critical sized Leyden jar which should excite no force when discharged through them is about  $1\frac{1}{2}$  "metres" or .00014 microfarad; i.e., smaller than the ordinary "pint" size.

With the help of an adjustable condenser, an instrument for measuring the  $L$  of well-insulated coils free from iron suggests itself here.

#### Ribbon Conductors.

If strips are used instead of round wires for the movable conductor, the electrostatic effect has an artificial advantage given it: for take a pair of similar strips, of length  $l$ , breadth  $b$ , and distance apart  $a$ , the force caused by a current  $c$  flowing through them with uniform intensity everywhere is easily calculated to be

$$\frac{4 c^2 l \mu}{a} \left( \frac{a}{\tan \alpha} + \frac{\log \cos \alpha}{\tan^2 \alpha} \right),$$

where  $\alpha$  is an angle whose tangent is  $b/a$ .

The quantity in brackets has a maximum value  $\frac{1}{2}$  when  $\alpha = 0$ , i.e., when the plates are far apart enough for their shape to be immaterial; and its value decreases steadily towards zero, viz.,  $\frac{1}{2} \pi \cot \alpha$ , as  $\alpha$  approaches  $90^\circ$ ; the whole becoming ultimately  $2 \pi \mu c_1 \cdot cl$ .

As for the electrostatic force between strips, I do not know how far we are justified in assuming uniform distribution of density, even if given uniform distribution of current; but at least when the plates are close together the force will not be very different from

$$2 \pi \cdot \frac{s v}{\kappa a} \cdot s v = \frac{2 \pi l}{\kappa b} \cdot (s_1 P c)^2;$$

the value of  $s_1$  being  $\frac{\kappa b}{4 \pi a}$ .

So the ratio of the forces for large close plates is

$$\frac{\kappa}{\mu} \cdot \left( \frac{P b}{4 \pi a} \right)^2 = \left( \frac{\text{No. of ohms in impedance of wire}}{120 \pi a/b} \right)^2.$$

Hence with strips six times as broad as their distance apart the forces will balance for a steady current when the interposed wire is only 60 ohms resistance.

#### Measure of "v."

In applying an experimental observation of this kind to a determination of the product of the ether constants  $\mu, \kappa$ , (and it just strikes me that it is after all only a modification of the method

by which Maxwell himself made one of the early determinations), it will be better to use round wires rather than strips, because linear dimensions then come in only under a logarithm, and moreover are such as can be measured with considerable accuracy without difficulty. Some of Mr. Boys's quartz-fibre and aluminium tube devices ought to permit the zero of force to be sharply got, and thus a good measure of "v" to be made.

We should have to observe very exactly the neutralisation of all force between the suspended and fixed conductors while a steady current was passing through them, with an interposed wire of known resistance, and then use the relation (3) or (3') in the form

$$\mu \kappa = s_1^2 R^2,$$

or

$$"v" = \frac{s_1}{\kappa} \cdot \frac{R}{\mu} = \frac{\text{resistance of wire expressed as a velocity}}{4 \log \frac{a}{\rho}}. \quad (7)$$

If the acting conductors are set very near each other,  $a$  being still the distance between their centres, the denominator alters itself a little, becoming

$$2 \log \frac{a^2 - 2 \rho^2 + a \sqrt{a^2 - 4 \rho^2}}{2 \rho^2},$$

with an easy additional complication if it is convenient to make the sectional radii unequal.\*

By filling the vessel containing the acting conductors with other insulating media, it is possible that the "a" for them could be directly measured.

#### Action of Moving Charges and Pulses.

So far I have not taken into account the sinuosity of distribution of Leyden jar discharges in space, nor the possibility of pulses passing the two portions of the circuit between which the force is being observed at different times or in different phases. It would seem as if a small assemblage of short-waved pulses sent round a long circuit might be prevented from exerting any mechanical action on each other if the adjacent parts of the circuit in which their action was to be observed were purposely separated by an intervening length of wire of many wave-lengths unsymmetrically introduced into the circuit. But before committing myself I should like to make a few experiments. Nevertheless I am tempted to go on a little further.

If, instead of considering pulses rushing along stationary wires, we consider charged wires moving along endways with the speed of light, Mr. Heaviside has attacked the general problem in the *Philosophical Magazine* for April, 1889. He there shows that between two planes perpendicular to a wire thus moving and moving with it at a distance apart equal to the length of the wire, the electrostatic intensity is

$$E = \frac{2 \lambda}{\kappa r},$$

and the magnetic intensity is

$$H = \frac{2 \lambda v}{r},$$

where  $\lambda$ , the linear density, may be distributed anyhow on the wire. Outside these two planes the force is zero.

If the two intensities were to act, one on a stationary charge of any number of electrostatic units, the other on a stationary magnetic pole of the same number of magnetic units, the two forces would be equal. If they act on a wire conveying a steady current, and charged up to a certain linear density, the forces will be equal when the statical measure of density is equal to the magnetic measure of current, i.e., when  $c = v \gamma$ ; for then

$$E \lambda = H \mu c.$$

Lastly, if the two forces due to one bit of charged wire, moving in its own line with the speed of light, act on another similarly moving piece, the current equivalent to the second wire will be  $v \lambda'$ ; and again there will be an equality between electrostatic and electrokinetic forces;

$$\frac{2 \lambda}{\kappa r} \lambda' = \frac{2 \lambda v}{r} \cdot \mu \lambda' v.$$

Not by any different  $\lambda$ , or by any rearrangement of  $\lambda$ , can the balance be disturbed: only by a different  $v$ . If either wire moves with velocity less than that of light, the electrostatic force overpowers the other, but, so long as the full velocity is maintained, the density on either wire may have any value, positive or negative without disturbing the balance; and this is natural enough, when, as here,  $\lambda$  and  $c$  vary together; for if  $\lambda$  be zero or negative anywhere,  $c$  is also zero and negative, and the balance persists.

Now proceed to the case of alternating pulses travelling along parallel stationary wires. Their speed of travel is the speed of light, and though the distribution of both density and current is sinuous there is nothing in that disturbing to a balance; moreover, so long as the waves are freely progressive,  $\lambda$  and  $c$  still accompany each other exactly, and nothing but a balance will be observed in a closed circuit, however, the phases operating in the acting portions be altered, if the right proportion holds between the current and the potential, as already calculated.

But if by reflection at distant unjoined ends of an open circuit the pulses be turned from progressive into stationary waves, then

\* See Foster and Lodge, *Phil. Mag.* June, 1875, p. 456.

localities can be found on the wires at which attraction or repulsion permanently occurs; for  $\lambda$  and  $c$  are no longer companions, the sinuous distribution of current lags a quarter period behind the sinuous distribution of charge. Hence at a given instant there will be places where the current force is a maximum and the static force zero; while at a quarter wave-length on either side the current force is zero and the static force a maximum. Halfway between these places only will the two forces be equal, but with alternate agreement and disagreement of sign. A readjustment of phase between the conductors will now make all the difference; a shift of a quarter wave-length changing from maximum to zero, and a shift of half a wave-length bringing about reversal of sign.

According to all this, therefore (if it be correct) it follows that the simple ideas on which Mr. Boys set to work are right after all, and that he will detect the forces in the way he expects.

#### Variation with Distance.

A few words as to the magnitude of the effect to be expected. Hertz has shown (see *Nature*, Vol. XXXIX., p. 404) that at a reasonable distance from a rectilinear oscillator, one or two wave lengths being practically sufficient, the electric force (or electromotive intensity) is perpendicular to the radius vector from middle of oscillator, and is of magnitude

$$E = \frac{q l q^2}{\kappa \rho} \cdot \sin(q\rho - pt) \cdot \sin\theta; \quad (8)$$

where  $\rho$  and  $\theta$  are the polar co-ordinates of the place, and  $q = 2\pi/\lambda$ .

Calling the length of the oscillator the axis, and the normal plane through its middle the equator, this means that the electric force is a maximum at the equator, diminishes towards the poles, and varies along any radius with the inverse distance from the centre.

At smaller distances the law is not so simple, but at any distance in the equatorial plane the electric oscillation is parallel to the oscillator, and of amplitude

$$\frac{q l}{\kappa r^3} \sqrt{(q^4 r^4 - q^2 r^2 + 1)},$$

showing that close to the oscillator the electric force varies as the inverse cube of the distance; at intermediate distances more slowly, while at a very few wave-lengths (practically one is sufficient) the first term under the root overpowers the others, and the ordinary law of the inverse distance holds good.

To get an idea of the magnitude of this intensity at any considerable distance from the axis, write  $q = sv$ , where  $v_0$  is measured by the length of spark employed at the oscillator, and

write for  $q^2$  its value  $\frac{\mu \kappa}{L s}$ ; then the amplitude of the electric force is

$$E = \frac{svl \cdot \mu \kappa \cdot \sin\theta}{\kappa \rho \cdot L s};$$

or, as  $L = 2l\mu \left( \log \frac{4l}{d} - 1 \right) = 2\mu lc$ , say,

$$E = \frac{v \sin^2\theta}{2rc} \quad (9)$$

Take as a numerical example any convenient oscillator, say, to avoid unnecessary repetition of specification, the small oscillator drawn to scale on page 54 of the *Philosophical Magazine* for July, 1889, which emits waves 1 metre long; let its constant  $c = 4\frac{1}{2}$ , and its spark be, as there quoted, 8 millimetres, so that  $v_0$  is about 26,000 volts. Then the initial electric intensity at a distance of a couple of wave-lengths in the equator is

$$E_0 = \frac{26,000 \text{ volts}}{18 \text{ metres}}$$

$$= 14.4 \text{ volts per centimetre.}$$

Putting, therefore, at this distance of 2 metres a parallel wire half a wave-length long as receiver, it utilises 50 centimetres of the above electromotive force, and gives a maximum sparking potential of 720 volts, which corresponds to a spark-gap of about a tenth of a millimetre between flat surfaces. This is an upper estimate, because time for a quarter-period's dissipation should be allowed, the result being multiplied by a dissipation factor  $\exp$ .

$\left( -\frac{4\lambda}{vs} \right)$ ; where  $R$  is to be found as follows.

#### Energy of Radiation.

The mean energy of the radiation per unit volume is, as is well known (Maxwell, art. 793),  $\frac{\kappa E^2}{8\pi}$ , which in the present case, abbreviating the characteristic factor,  $\left( \log \frac{4l}{d} - 1 \right)$  or its equivalent, to  $c$ , is,

$$\frac{\kappa}{8\pi} \cdot \frac{v^2 \sin^2\theta}{4\rho^2 c^2} \quad (10)$$

The energy sent per second through the sphere of radius  $\rho$  with velocity " $v$ ," is

$$\begin{aligned} & \int_0^\pi 2\pi\rho \sin\theta \cdot \rho d\theta \cdot \frac{\kappa v^2 \sin^2\theta}{32\pi\rho^2 c^2} \\ &= \frac{4}{3} \cdot \frac{\kappa v^2}{16 c^2} \\ &= \frac{v^2}{12\mu v c^2} \quad (11) \end{aligned}$$

And this is the rate at which the oscillator radiates energy during its activity. Comparing (11) with (10) we see that the equatorial radiation exceeds the mean radiation in the proportion of 3:2.

The difference of potential  $v$  is not constant, but decreases logarithmically according to the law

$$v = v_0 e^{-\frac{t}{R}};$$

where  $R$  is a dissipation-coefficient of the dimension of resistance, and of value easily found, thus:—

Total energy radiated for every spark of the oscillator is

$$\int_0^\infty \frac{v_0^2 e^{-\frac{2t}{R}}}{12\mu v c^2} dt = \frac{1}{2} \frac{v_0^2 \cdot R}{12\mu v c^2},$$

which must also equal  $\frac{1}{2} v_0^2$ , the initial energy; hence

$$R = 12\mu v c^2 = 360 c^2 \text{ ohms.}$$

Taking as a numerical example the same oscillator as above, with  $c = 4\frac{1}{2}$  and  $v = 88$  electrostatic units, all these values are easily estimated. For instance, the mean energy of the radiation per unit volume at any considerable distance  $r$ , say 2 metres, in the equator, is

$$\frac{\kappa v^2}{32\pi c^2 r^2} = \frac{88 \times 88}{25 \times 81 r^2} = \frac{3.8}{r^2} = \frac{3.8}{4 \times 10^4} \text{ barads}$$

= 95 microbarads, at a distance of two metres.

This will cause a momentary pressure on a metallic surface normally exposed to it, of 95 microdynes per square centimetre, or a milligram weight per square metre; and is nearly twice as strong as full sunshine while it lasts.

At 1 metre distance, I need hardly say, the energy and pressure are four times as great.

The area of energy absorbed by a fine wire linear receiver may be estimated roughly by finding the closeness of a grid of parallel wires which would just not let any radiation pass through it. Suppose, for instance, that a grid with wires 10 centimetres apart satisfies this condition; then each wire mops up energy for a breadth of 5 centimetres on either side of itself. The heat generated in such a wire at each spark is

$$\frac{3}{2} \cdot \frac{b l}{4\pi r^2} \cdot \frac{1}{2} s v_0^2.$$

This, in the numerical case already taken, with  $\frac{s}{\kappa} = 1.4$  centim.

and  $\kappa v_0^2 = (88)^2$  dynes, gives, at a distance of 1 metre,

$$\frac{3 \times 590}{25 \times (100)^2} \times 7 \times (88)^2 = 32.5 \text{ ergs per spark;}$$

which, repeated 100 times a second by a suitable contact-breaker, would yield 3,250 ergs per second, or 1 ordinary thermal unit every  $3\frac{1}{4}$  hours.

The dissipation-factor, mentioned at the end of last section, is

$$e^{-\frac{100}{1.4 \times 12 \times 81}}$$

#### Attempt at further detail.

To work out more completely what happens when one oscillator is used to excite another arranged parallel to it at an equatorial distance  $r$ , not near enough to re-act, I suppose we may consider the receiver as subjected to an impressed E.M.F. given by (8), and write down the equation to its current  $x$  at any instant,

$$x + 2\kappa \dot{x} + n^2 x = \frac{l' v_0 e^{-m't} \sin(qr - pt)}{2rc} \quad (12)$$

the solution of which is given (for instance) in Lord Rayleigh's "Sound," Vol. I., p. 62.

The heating of the receiver at each spark will be  $\int_0^\infty R' \dot{x}^2 dt$ .

If there be two such receivers, far enough off each other not to encroach on each other's field, the current attraction between them will be proportional to  $x_1 x_2$ , and the static repulsion to  $x_1^2 x_2^2$ .

Calling the right-hand side of the above equation  $v$ , and writing  $n'^2 - \kappa'^2 = n^2$ , the complete solution is

$$\begin{aligned} x &= \frac{1}{n} \int_0^t e^{-\kappa(t-t')} \sin n(t-t') \cdot v' dt' \\ &+ \frac{e_0}{\cos} \cdot e^{-\kappa t} \cos(n t - \gamma); \quad (13) \end{aligned}$$

where  $v'$  is the same function of  $t'$  that  $v$  is of  $t$ , and where

$$\tan \gamma = \frac{x_0}{nx_0} + \frac{\kappa}{n}.$$

The second term in the above, which expresses free vibrations in the receiver, may be made zero, because it contains the initial disturbance of the receiver as a factor; and the first term, which expresses forced vibrations, simplifies down to

$$x + c = \frac{l'v_0}{4nrc} e^{-mt} \left( \frac{\sin \alpha}{p-n} \cos(qr-pt+\alpha) - \frac{\sin \beta}{p+n} \cos(qr-pt+\beta) \right), \quad (14)$$

where  $\tan \alpha = \frac{p-n}{\kappa-m}$ , and  $\tan \beta = \frac{p+n}{\kappa-m}$ .

If there is anything like agreement between the natural periods of vibrator and resonator, the first of these two terms overpowers the other.

Another way of writing the solution is

$$x + c = \frac{l'v_0}{4rcn} \frac{\sin(\beta-\alpha)}{\kappa-m} e^{-mt} \sin qr - pt + \alpha + \beta. \quad (15)$$

#### Appendix.

It is in accordance with theory to assert that the action of two given magnets on each other varies inversely with the permeability of the medium; that the action of two currents on each other varies directly as the permeability of the medium; and that the action of a current on a given magnet is independent of the properties of the medium.

To avoid misunderstanding, it must be perceived that the statement refers to a given magnet, not to a magnet of numerically specified strength, because about that there would be some ambiguity according to the medium in which it was measured.

Similarly, the static action between two charges is inversely as the dielectric constant of the medium; the action between a given charge moving at the approximate light speed and a given magnet is independent of the medium, except in so far as its properties affect the velocity of light; while the dynamic action between two given charges moving together at the light speed is proportional to the permeability.

It may be as well to have direct experimental verification for some of these things.

#### LEGAL.

**Watt v. Maxim-Weston Company, Limited—Maxim-Weston Company, Limited v. Watt.**—On Wednesday, before Mr Justice Vaughan Williams (vacation judge), sitting in the Chancery Division of the High Court of Justice, Mr. E. Morten applied *ex parte* in the above actions, which would shortly come before Mr. Justice North for trial, for an order for the examination of a witness before a special examiner. The actions involved a great many issues, one important thing being to unravel the dealings which had taken place in the shares of the company at the instance of Mr. Watt, the chairman of the company. For this purpose it would be necessary to have the evidence of the stockbroker who carried out the transactions on the Stock Exchange for Mr. Watt. Information had been just received that Mr. Barnard, the stockbroker in question, was about to depart for America in search of sport, which was likely to keep him there for the next six months. That being so, it was desired to take the examination early next week. In the case of *Bidder v. Brydges*, the Court had held that such an order would be made where necessary for the purposes of justice.

HIS LORDSHIP said he was somewhat loth to make the order *ex parte*, but he would do so upon conditions. It was quite plain the examination could not be conducted effectively unless the other side had notice and the opportunity of being present. The order would go, but would contain upon its face the condition that notice should forthwith be given to the other side, and that they should be at liberty to apply to discharge the order.

**Woodhouse and Rawson, Limited.**—A motion for the removal of the liquidators of this company, for the appointment of others in their place, and to restrain further dealing with the assets, was in the list for hearing, but Mr. Baker stated that, by consent, it had been arranged that the motion should be withdrawn from the paper, no order being made upon it.

HIS LORDSHIP acceded to the application.

**The City Lighting.**—The City Commissioners of Sewers, at the instance of the Streets Committee, on Tuesday, resolved to invite tenders for lighting by electricity the western districts of the City on similar conditions to those arranged for the east and central districts, but intimating that should any deviation from such conditions favourable to the Commissioners be desired by the companies tendering, such deviation must be specifically set forth.

#### NOTES.

**Electric Lighting in Hampshire and Sussex.**—The electric light is making considerable progress in Hampshire and Sussex. At Portsmouth, the special committee which has been appointed to consider the steps to be taken to introduce the light into the borough, are about to retain the services of an eminent electrician. The Winchester Council have determined to send a deputation to Fareham, where the electric light is in full operation. At Lewes last week a public meeting of the ratepayers was convened by the mayor for the purpose of considering the question of street lighting. A long discussion ensued, and eventually it was determined to adjourn the matter for a fortnight.

**Electric Lighting in Pemberton.**—The Local Board of Pemberton, in Lancashire, are just now having a portion of their district lighted by electricity by way of experiment; and it is understood that if the experiment—which will extend over two months—is of a satisfactory character, this means of illumination will be adopted in substitution for gas. Messrs. Mercier and Corlett, of Wigan, have put down the plant for this experiment. Lighting commences at dusk and continues until 10 o'clock.

**Electric Lighting in Nelson.**—The Gas Committee of the Nelson Corporation have under consideration a scheme for the lighting of the town by electricity instead of gas as at present.

**Lighting at Northampton.**—The central station of the Northampton Electric Light and Power Company, Limited, is being erected by Messrs. Crompton and Co., Limited, who are also doing the wiring of the hotels, houses, shops, &c., to be lighted. Mains are already laid in several of the streets and current will shortly be available.

**The Electric Light at Exeter.**—The Exeter City Council held a meeting on Monday to consider an application from the Electric Light Company and a recommendation from the special committee on electric lighting that steps should be taken to obtain a provisional order for the Council. Mr. Alderman Andrew proposed: "That, inasmuch as any monopoly of the supply of electric light was rendered impossible by the Acts of 1882 and 1888, which also safeguard the interests of the citizens in other directions, it is not desirable that the Council should take steps to obtain a provisional order until it has ascertained what arrangements can be made with the existing Electric Light Company for the optional purchase by the Council of their works at shorter specified periods than 42 years." He reiterated a statement which he had previously made, that if the Authority obtained the necessary powers from the Board of Trade it would cost them £30,000. Mr. Pope seconded the amendment, which, after a discussion, was adopted by 28 votes to 13. A small committee was appointed to confer with the Electric Light Company and go into all matters of detail.

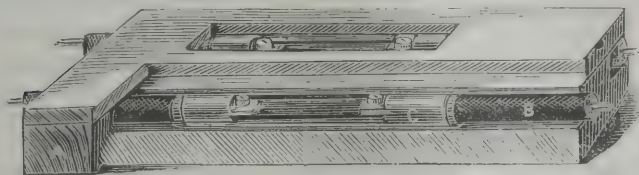

**Electric Lighting in Chelsea.**—The figures given by the surveyor in the vestry's annual report and published by us are rather ancient. The houses taking current have increased to 180, and, including those in South Kensington, represent 17,300 candle-power.

**Electric Lighting in Leeds.**—At a meeting of the Leeds County Council, on Monday, it was decided to leave the lighting of the Borough to private enterprise.

**Exhibition at Palermo.**—It is announced that a national exhibition will be held at Palermo during the coming year. The committee has determined to make the electrical portion of the exhibits a feature of much greater importance than was the case in the exhibitions at Turin and Milan.

**The Proposed Spanish Cables.**—The issue of *Industries* for the 3rd October contains the following note with regard to the telegraph cables to the African coast:—"Two tenders have been sent in to the Spanish Government for the laying of the cables from the coast of Spain to the African possessions in Morocco. One of the tenders is from the India-Rubber, Gutta Percha, and Telegraph Company, London, and the other from the Spanish National Company. Neither of the tenders agreed strictly with the bases that were required by the Government, and it seems likely that they will be rejected. The administration would have preferred to receive a tender from Messrs. Siemens, but this firm would not have agreed to such risky conditions as the Government demanded. The fact is that the cables to the other side of the Strait have a bad history." Our contemporary would have added considerably to the interest with which this note will be received had some authority for the last paragraph been given. The history of cables across the Strait would be a valuable addition to the records of submarine telegraphy.

**The Champion Cut-out.**—Under this name, Mr. J. Torr Todman is making a cut-out which can be placed in the ordinary wood casing which covers the cable, thus avoiding the necessity for cut-outs projecting from the walls. In the figure, A is the wood casing, B the cable, C the cut-out, consisting of two brass ends in

which the cable is soldered. These two ends are joined by a strip of vulcanised fibre, and the fuse wire is fixed under the two screws shown. The fuse and connection is covered by a glass tube which slides along the cable when it is necessary to renew the fuse.

#### Recent Interruptions and Repairs to Submarine Cables and Land Lines:—

	Interrupted.	Repaired.
Cable :—Jamaica—Colon...	16 July, 1890.	4 Sept., 1890.
Amoy—Shanghai	21 " "	3 Aug., "
Buenaventura—		
Santa Elena ...	30 Aug. "	7 Sept. "
Suez—Suakim ...	12 Sept. "	13 " "
Suakim—Perim ...	12 " "	Still interrupted.
Land Line :—Buenaventura	10 Sept. "	13 Sept., 1890.
Moulmein—Bangkok ...	14 " "	16 Sept. "

**The Proposed Electric Tramways in Glasgow.**—On Monday, September 29th, a deputation from the Glasgow Corporation, consisting of Bailie Paton (convener of general committee), Bailie Wallace (sub-convener of general committee), Bailie McFarlane, John Ure, Dean of Guild, and ex-Lord Provost, Councillor Colquhoun, and Mr. David Rankine, engineer, Glasgow Corporation Tramways, visited the General Electric Power and Traction Company's electric cars and installation on the Barking Road section of the North Metropolitan Tramways Company's system. The deputation were met by Messrs. Fuller and Macpherson, directors of the Electric Power Company, and by several of its leading officials. Having made a minute inspection of the many points of interest in the working of the cars, the corporation authorities expressed themselves as greatly pleased with all they had seen. The *raison d'être* of the visit was, that the Glasgow Corporation have it in view to take into their own hands, at the expiration of the present concession, the entire Glasgow tramway service, and equipping the same with accumulator cars. On the following day the deputation visited the installation of the Central Birmingham Tramway Company.

**Another Fatal Shock.**—A telegram from New York, dated October 5th, states that a man was killed in New Orleans the preceding day through coming in contact with an electric light wire.

**Account of a Cable Expedition.**—The October number of *Scribner's Magazine* contains an account, written by Mr. Herbert Webb, of the laying of the cables connecting Spain with the Canary Islands. It was scarcely necessary to disguise the names of the vessels employed, since the names of the islands, to which the cables were laid, are given. This, however, is but a minor consideration, and in no way detracts from the merits of the article in question. Some of the difficulties met with in cable work are well described, and we may congratulate Mr. H. Webb on having written a popular account of some of the incidents connected with submarine telegraphy. The article is sufficiently well illustrated.

**The Advantages of Technical Education.**—The students of the Glasgow and West of Scotland Technical College appear to be doing well, especially in the engineering classes under Prof. A. Jamieson. Mr. James Raeburn, who attended the electrical engineering laboratory, has been despatched to St. Petersburg to settle details about the electric lighting of Odessa Harbour, the Russian Government having approved of his plans prepared for the Thomson-Houston Company, who are giving him £500 per annum. Mr. Arthur H. Allen, who gained first-class honours in both electricity and electric lighting last session, has entered the service of Messrs. Holmes and Company, of Newcastle; and Mr. Auchinachie, from Keith, has been given a good appointment with the well-known firm of Messrs. Siemens Brothers & Co., of London and Charlton.

**O. S. A. Annual Dinner.**—The sixth annual dinner of the Old Students' Association of the City Guilds of London Institute will be held at the Holborn Restaurant on Friday, October 17th, 1890, at 7 p.m. Tickets, price 4s. 6d. each, may be obtained from the secretary, 14, Garfield Road, Lavender Hill. Mr. W. B. Esson is the president of the Association for the ensuing session.

**The Postmaster-General and the Case of Senior Telegraphists.**—The following notice was posted in the Central Telegraph Department on Saturday last. "In continuation of the notice of the 14th July, the Postmaster-General desires to notify that, with the consent of the Lords of the Treasury, he has converted 43 of the existing senior telegraphists appointments on the male staff into a new body of second class assistant superintendents on a scale of £200, rising, by £10 annually, to £260. The minimum of the senior class of telegraphists will be £160 per annum." Twenty corresponding appointments will be made on the female staff. Curiously enough, these new appointments are dated Sunday, October 5th, and this very unusual circumstance has given rise to much speculation and conjecture.

**The School of Electrical Engineering and Submarine Telegraphy.**—As the result of the examinations recently held at the above school, we are informed that the following gentlemen have now obtained the Vellum Certificate of the school:—(a) In electric lighting and power transmission—Messrs. Claypoole, Garré, Gillies, Lawrence, Phillips, Roussel and Waring. The examinations in these subjects were conducted by Mr. Gisbert Kapp, and included a *viva voce* and practical examination. (b) In telegraphy and telephony—Messrs. Lawrence (above named) and Salmony. This examination was conducted by Mr. H. R. Kempe.

**Movements of Cable Ships.**—On the morning of Wednesday, October 8th, the s.s. *Silvertown* left the Silvertown Company's works, en route for the West Coast of America, to lay direct cables between Lima, Yquique, and Valparaiso.

H.M. telegraph ship *Monarch* sailed for the Irish Channel to repair one of the Post-office cables.

The s.s. *John Pender* left the river for, we are informed, the Red Sea, to relieve the cable steamer at present stationed there.

**The Manchester Association of Engineers.**—We notice in the syllabus of the 1890-91 season of the Manchester Association of Engineers that on January 24th next, Mr. A. B. Blackburne, assistant manager to Messrs. Mather and Platt's electrical department, is announced to read a paper on "Dynamos: the Consideration of the Chief features which Regulate their Application." We hope that Mr. Blackburne's latest experiences will enable him to put before his audience something new; in any case, his discourse is certain to prove interesting.

**Anticosti Cable.**—Messrs. W. T. Henley's Telegraph Works Company, Limited, write to us as follows:—"Referring to the paragraph under this heading in your "Notes" in the issue of the 3rd inst., we beg to inform you that this cable was made by us, the core being composed of our patent ozokerited vulcanised India-rubber, of which the Canadian Government have had considerable experience for some years past."

**A Gallant Deed.**—IN the REVIEW for September 19th, we chronicled the death of lineman Kepp, in New York, but there was an incident connected with this matter which has only just come to our notice through the columns of *Modern Light and Heat*, and which we have much pleasure in bringing before our readers. Our contemporary says:—"The electric lineman must beware of the live wire. If he is possessed of ordinary intelligence and presence of mind, and is thoroughly instructed in the duties and requirements of his calling, as every lineman should be, any accident which may befall him must be the result of his own negligence or hardihood. The death of lineman Kepp, and the gallant but too late rescue of the suffering man by Mr. Charles Phipps, of the Brush Company, illustrate this. Had the unfortunate lineman taken the ordinary precaution of using rubber gloves, he would have been alive to-day. Mr. Phipps's heroic act was fraught with much greater danger than that which menaced the lineman. He was coming out of the theatre in evening dress, and with rare presence of mind took in the whole situation at a glance. He had no rubber gloves, but he improvised a substitute with rubber coats borrowed from hackmen. Thus protected, he climbed the pole and cut the wire across which the lineman hung, after which he lowered the man into the arms of those who were waiting and watching below. Although Mr. Phipps made light of his brave action, those who saw it were more appreciative, and we believe that the gold medal of the Humane Society has been awarded to many not more deserving than the noble-hearted electrician."

**Opening for Electric Traction.**—Colonel C. M. Davidson, the chairman of the Hawaiian Tramways Company, stated at the meeting of the company last week that the "board were doing their best to keep down the expenses of the company, and with that view they were considering the advisability of running their tramway by electricity." English traction companies should attend to this.

**The National Telephone Company.**—We hear that the directors of the National Telephone Company, Limited, have decided to reduce their rates of £15 to £10 per annum, and that they are further considering the question of giving special advantages to their subscribers for trunk line service.

**Dublin City Lighting.**—The time for receiving tenders has been extended to the 30th October.

**Killarney in the Running.**—The Town Commissioners, after various flights of oratory, have again settled on the earth, and will apply for a provisional order in a reasonable manner.

**Electric Light at Gravesend.**—After many discussions the Town Council has resolved to apply for a provisional order.

**Electric Traction.**—At the usual meeting of the Oswaldtwistle (Lancashire) Local Board, on Monday, consent was given to Mr. Chadwick, C.E., constructing an electric tramway through that township to Accrington on satisfactory terms being arranged.

**Personal.**—Last week the electrical engineering pupils of Messrs. Immisch & Co., Kentish Town, presented a piece of silver plate, as a token of their esteem, to Mr. Charles Francis Quicke, late chief engineer and works manager, on his relinquishing that post, after eight years' connection with the firm. The workmen and staff also presented, on their own behalf, a massive silver spirit case and an inlaid cabinet.

Mr. G. Jones, electrical engineer at Chatham Dockyard, has been ordered to proceed to the works of the Naval Construction and Armament Company, Barrow-in-Furness, to assist Mr. Apsey, who recently proceeded from this yard to superintend the construction of the electric light apparatus which is being manufactured for vessels of the Royal Navy.

**Electric Light Accidents.**—A correspondent of the *Times* says an engineer in the electric light works at Waltham, in Massachusetts, last Thursday received an electric shock of 1,500 volts. His hands were badly burnt, but his injuries were otherwise not serious. Although he was, perhaps, working a 1,500-volt circuit, it does not follow that a current passed through him at that difference of potential,

**A Correction.**—A correspondent says our note last week, on "A Telegraph Superintendent Killed," was exaggerated; the man is still dead.

**Edinburgh Exhibition.**—At a committee meeting held last week in the City of London, it was resolved to consider the exhibition a success. Over three million people have passed the turnstiles, a fact which is probably due to the near vicinity of the Forth Bridge.

**The Revolution in Copper.**—On Thursday, the 25th September, Dr. John Hopkinson paid a visit to the works of Elmore's Patent Copper Depositing Company, at Leeds. His time was limited, so his report simply states that he had an opportunity of observing the effect of the burnishing tool upon the deposited copper which, under its influence, exhibited a beautifully smooth surface. He also confirms his previously expressed opinion that on a large scale the Elmore process of depositing should not exceed £5 a ton or  $\frac{1}{2}$ d. per lb., and he returned well satisfied with what he saw. A report from Dr. Hopkinson, or any other qualified expert, giving a comparison of the actual cost of the Elmore and other processes for producing copper tubes would have been to the point, and have put us in possession of hard facts instead of estimated data with which we have hitherto had to content ourselves.

**The Channel Telephone Cable.**—We understand that Messrs. Siemens Bros. & Co. have secured the contract for manufacturing the 4-cored cable to be used for telephoning across the Channel. -

**Woodhouse and Rawson United, Limited.**—The report and balance sheet of this company is before our readers, and the meeting to discuss the same takes place to-day. It would, of course, be very interesting to know how the gross profit of nearly £100,000 was made, how much from trading, and how much from company promoting. The shareholders, however, will doubtless be content with their 15 per cent., and we sincerely trust that so good a dividend will be always forthcoming.

**Edinburgh and the Electric Light.**—At a meeting of the Edinburgh Town Council on Tuesday, it was resolved, on the motion of the Lord Provost, to make application to the Board of Trade for a provisional order.

**The Nicaragua Canal and the Telegraph.**—In connection with the works on the Nicaragua Canal, which are stated to be progressing most favourably, we learn that a telegraph line has been completed between Greytown and the Lake of Nicaragua, where a junction is made with the telegraph lines to the Pacific Coast. We therefore presume that telegraphic communication is now established between Greytown and the United States *via* the Central and South American Company's cables which touch at San Juan del Sur, a port on the Nicaraguan coast, and connected by Government lines with the principal towns in that Republic.

**Berliner's Gramophone.**—Several gramophones of this make have, during the past three weeks, been shown in operation at 11, Queen Victoria Street, E.C. It is not unlikely that we may hear more of this invention shortly from a company point of view.

**Electric Railway Experiments.**—Some experiments have been made with a railway waggon fitted with motors and accumulators, on the local railway Hildburghausen-Heldberg-Friedrichshall, in Bavaria. The line is about 19 miles long, and the waggon is said to have worked successfully. This is the greatest test with electric traction in Germany. The experiments were made by the builder of the railway, Mr. Hostmann and two other engineers, one being from the Oerlikon Engineering Works.

**The Report of the Postmaster-General.**—The report of the Postmaster-General, issued last week, shows a great increase of business. Telegraphic money orders issued during the month of March amount to £6,262. In the course of the year 263 post-offices and 58 railway offices were opened for telegraphic business, making the total number of such offices open on the 31st March 5,673 and 1,679 respectively. The total number of telegrams dealt with was 62,403,399, as compared with 57,765,347 in the previous year.

## NEW COMPANIES REGISTERED.

**Leeds and London Electrical Engineering Company, Limited.**—Capital £100,000, divided into 250 founders' shares, 9,750 non-cumulative £7 per cent. preference shares, and 10,000 ordinary shares of £5 each. Objects: To form centres in the United Kingdom and elsewhere at which electrical energy may be generated and accumulated, and from which the same may be distributed for public and private lighting of every description, or for supplying motive power or heat, and to enter into contracts for such purposes. To acquire the right to manufacture and put up telephones, telegraphs, electric bells, phonographs, and all other electrical apparatus now known or hereafter to be invented. To manufacture lightning conductors, electrical generators, motors, cables, accumulators, lamps, and fittings of all kinds. Signatories (with 1 share each): H. Linklater, 5, Benthall Road, N.; T. B. Arundell, 1, Devonshire Street, Portland Place; P. H. Clark, 51, Norroy Road, Putney; James Whitehead (electrical engineer), Heycot, Crouch End, N.; J. A. Roxburgh, 77, Queen's Road, Finsbury Park; J. Kerby Chambers (electrical engineer), 10, Richmond Villas, Holloway; J. W. S. Hawes, 25, Colebrooke Row, N. The signatories are to appoint the first directors; qualification, £500 in shares; remuneration, one-tenth of the net profits after payment of 7 per cent. dividend on preference and ordinary shares, provided that the maximum remuneration be £1,500 per annum. Registered 2nd inst. by Wilson & Co., 1, Copthall Buildings.

**Electro-Metallurgical Company, Limited.**—Capital £2,500, in £5 shares. Objects: To acquire the business of electro-metallurgists, platers and depositors on metals, carried on by the Electro-Metallurgical Company at 23, Newhall-street, Birmingham, and the business of electro-platers carried on by the Victoria Plating Company at 9 and 10, Sherborne Road, Balsall

Heath, Birmingham. Signatories (with 1 share each): \*Alfred Smallwood, \*Alfred Gough, \*H. Fenney, Wm. Ralph Bradley, J. J. Bedney Arter, J. H. Fenney, E. G. Walters, all of Birmingham. The signatories denoted by an asterisk are the first directors. Registered 3rd inst. by T. H. Philpots, 89, Chancery Lane, agent for Alfred Gough, 120, Edmund-street, Birmingham.

**Buller's, Limited.**—Capital £200,000, in £10 shares. Objects: To acquire the business and liabilities of Buller, Jobson & Co., Limited (in voluntary liquidation), engineers and contractors. To manufacture and produce electrical plant, and to supply electric and other forms of power and energy. Signatories (with 1 share each): \*E. W. Buller, 49, Charlotte Road, Birmingham; \*H. C. Jobson, Kidderminster; E. J. Chambers, Dudley; W. Greenhill, Dudley; E. P. Jobson, Dudley; A. T. Buller, Penrith; J. T. Harris, Stone, Staffordshire. The first two signatories are appointed directors; qualification, 100 shares. Registered 6th inst. by Waterlow Brothers and Layton, Limited, agents for Smith, Pinsent and Co., of Birmingham.

## OFFICIAL RETURNS OF ELECTRICAL COMPANIES.

### Patent Lithographic Zinc Plate Company, Limited.

—The statutory return of this company, made up to the 20th August, was filed 6th September. The nominal capital is £10,000 in £5 shares; 700 shares are taken up, 200 being considered fully paid. Upon 500 shares £3 per share has been called and paid. Registered office, India Chambers, Queen's Dock Side, Hull.

**J. A. Egestorff and Company, Limited** (manufacturers of ultramarine and colours and electrical engineers).—The statutory return of this company, made up to the 29th August, was filed September 4th. The nominal capital is £10,000 in £5 shares; 1,290 shares have been taken up, 400 being considered fully paid. Upon 890 shares, £2 10s. per share has been called, the calls paid amounting to £1,509 10s., and unpaid to £715 10s. Registered office, Backbarrow, near Ulverston.

**Buller, Jobson and Company, Limited.**—At an extraordinary general meeting of the members of this company, held at the Great Western Hotel, Birmingham, on 16th ult., it was resolved to wind up voluntarily, the liquidator, Mr. W. Newton Fisher, of Waterloo Street, Birmingham, chartered accountant, being authorised to enter into an agreement with a new company to be called Buller's, Limited, for the transfer to that company of the assets and liabilities of this company. These resolutions were confirmed on the 2nd inst. and were duly filed on the 3rd inst.

The last return of the company is made up to the 10th February; the nominal capital at that date was £108,100 divided into 5,405 "A" and 900 "B" shares of £20 each. 4,505 "A" and 900 "B" shares have been taken up and the full amount has been called thereupon. Upon 4,497 "A" and 900 "B" shares the full amount is considered as paid up. The calls paid amount to £160. At a meeting of the company, held on the 7th March, the capital of the company was increased by the sum of £50,000, divided into 2,500 first preference shares of £20 each, carrying a cumulative dividend of 6 per cent per annum.

**Kent Patent Arc Lamp Company, Limited.**—The subscribers to this company have appointed as directors of the company Mr. Herman Stanberg, of 45, High Street, Borough, S.E., and Richard Dyson, of 15, Australian Avenue, E.C. The registered office of the company is now situated at 17, Holborn Viaduct. Secretary, Mr. Arthur Salter.

**Baxter's, Limited** (civil, marine and electrical engineers).—The statutory return of this company, made up to the 29th July, was filed 23rd August. The nominal capital is £30,000, divided into 1,000 preference and 5,000 ordinary shares of £5 each. 14 ordi-

many shares are taken up, and £4 has been called and paid thereon, the calls paid amounting to £56. Registered office, Sandiacre, Derby.

**Peru Telephone Company, Limited.**—The registered office of this company is now situate at 42, Old Broad Street, E.C.

**Ecuador Telephone Company, Limited.**—The registered office of this company is now situate at 42, Old Broad Street, E.C.

## CITY NOTES, REPORTS, MEETINGS, &c.

### Woodhouse and Rawson United, Limited.

THE annual report of the directors to be laid before the meeting at Winchester House to-day (Friday), the 10th inst., states:—Of the original capital all the ordinary and preference shares have now been issued. Of the ordinary shares, one-half of their value remains uncalled. The premiums from the second issue, amounting to £4,050 5s. have been placed to a reserve fund. From the balance sheet it will be seen that after payment of all expenses and writing off £7,421 16s. 9d. in reduction of the sum standing to patent account, the balance to the credit of the company amounts to £61,085 1s. 9d. Out of this sum the directors propose to pay a dividend at the rate of 15 per cent. per annum on the ordinary shares and of 8 per cent. per annum on the preference shares, which, together with the interim dividend for the half-year already paid at these rates, amounts to £18,749 6s. 6d. Of the balance, amounting to £42,335 15s. 3d., the directors propose to place to reserve £25,000, of which £10,000 will be set aside to a goodwill reserve fund, and £15,000 to a general reserve fund, and to apply £1,000 to the formation of an *employés* pension fund, leaving £16,335 15s. 3d. to be carried forward to next year's account. The directors do not propose to increase the dividend anticipated in the prospectus, as the prudence of building up reserve funds of a considerable amount will be evident to the shareholders.

The directors think it well on this occasion to give more information than is usually contained in an annual report, in order to enable the shareholders to realise the scope and extent of the operations in which the company is engaged. Their efforts during the past year have been directed to consolidating and extending the several branches of business which have been taken over by the company. These are of a very comprehensive character, and include:—

1. The manufacture of all articles connected with electricity and engineering, so far as they come reasonably within the technical and financial resources of the company.

2. The supply of all articles connected with electricity and electrical engineering.

3. The execution of all works of installation coming within the province of electrical engineers and contractors.

4. The testing and proving of new patents and inventions connected with electrical and engineering science, and their introduction to the public, either by arrangements for working such inventions by this company or by assisting the owners in forming separate companies for working them.

The experience of the past year leaves no doubt that great services may be rendered to the shareholders and to the public by developing this latter branch of the business, with prudence and energy; and the knowledge acquired from an extensive range of manufactures, and a thorough acquaintance with the demand and channels of supply of electrical plant and apparatus, place this company in an exceptional position to invite and secure the confidence of inventors, and to assist them in bringing their inventions before the public. With this object it is necessary to command the ready means of practically testing every kind of electrical and mechanical invention which may be offered, and to maintain an extensive business and correspondence in all parts of the world.

The following are the factories owned by the company and the character of the work done:—

a. West Kensington Hall Works, Hammersmith Road, W. These works, over an acre in extent, are the company's freehold. Here are manufactured light goods, such as switches, lamps, measuring and other electrical instruments, primary and secondary batteries, and every class of small automatic machinery. Here also is carried on the electro-plating business and manufacture of plating plant. At these works most processes offered to the company are tested, and only when they have thoroughly passed the examination of the company's experts is the purchase or introduction to the public entertained. At the present moment four important electrical inventions of exceptional merit are undergoing the process of final testing.

b. Union Foundry, Kidsgrove, near Crewe. These works, which are also freehold, have been recently acquired on advantageous terms, and are well situated in the heart of the coal and iron district, having both a railway siding and a canal adjoining. They are fitted up with every class of heavy machinery to enable the company to construct engines and boilers of almost any size or power, water and gas works plant, steam and hydraulic cranes, tanks, pumps, large dynamos and other heavy machinery, whilst

further special plant is now being erected to keep abreast of recent improvements.

c. Cornbrook Telegraph Works, Manchester. These works are leasehold, and are fully engaged in the manufacture of telegraphic instruments; there are also manufactured small dynamos and motors, as well as light lathes and drilling, shaping, milling and screwing machines, specially designed for electrical work. Practically the whole of the contracts for telegraphic instruments, &c., for the London and North Western Railway for a period of two years, together with contracts for the Caledonian and Great Eastern Railway Companies, have been placed with the company at these works.

d. The supply department is rapidly increasing its turnover. Its catalogue of electrical goods and appliances connected therewith is recognised as the most complete and comprehensive of its kind, and forms a standard text book in the trade. The acquisition of the new warehouse, with entrance at 30, Cannon Street, and more recently of the lease of the neighbouring premises at 34, Cannon Street, and 84, Queen Victoria Street, enables the company to keep in hand and exhibit an extensive stock of nearly every kind of electrical apparatus and fittings.

e. The installation department has carried out a large number of important contracts. Among others, the lighting of the palace at Mysore, India, by electricity has been satisfactorily and profitably finished; and the Sociedad Española del Electricidad, in Barcelona, has placed the whole of their arrangements for improving and extending the lighting of that city by electricity in the hands of this company.

f. At Bradford the company have a branch establishment, with show room and warehouse, which provides for installations and the supply of electrical goods in the North of England. The company has been specially appointed contractors to the local authorities in that town in connection with their central electric lighting station.

g. An electric bell and signalling business is conducted at 2, Gray's Inn Road, under the management of the Messrs. Jensen, whose well-known patents this company has acquired.

h. The company has also acquired the electric and steam launch business of Mr. Sargeant, carried on at Chiswick.

Branch offices have been opened during the year in Sydney, Melbourne, Johannesburg, and Valparaiso, besides additional agencies in various other foreign countries. In the early part of the present year the directors disposed of a portion of their premises at West Kensington to the Kensington Co-operative Stores, Limited, a new company, which obtained the support of this company because it afforded an opportunity of disposing, upon advantageous terms, of a portion of its buildings unsuitable for manufacturing purposes, and increased the value of the remainder of the property. A second issue of shares of the Kensington stores has lately been made at a large premium, and was applied for two and a half times over. The directors have, in addition, been instrumental in forming the International Okonite Company, for the working throughout the world of the patents for that valuable insulating material. The company, whose shares have been entirely allotted, has an established business in America of a profitable and rapidly increasing character, and owns works also at Manchester, from which it will supply the okonite wire required in Great Britain. The yield of both the American and English works during the current year has largely increased, and a profitable return may be looked for. This report would not be complete without an allusion to the success that has attended the introduction by Woodhouse and Rawson, Limited, of the now well-known Elmore process for manufacturing copper articles by electro-deposition at a great saving of cost, and of unique quality. Since the expiration of the financial year ending on the 30th June, 1890, this company has introduced Elmore's French Patent Copper Depositing Company with very marked success; 66,750 shares were offered for subscription, and over 250,000 shares were applied for. The official quotation of the shares of this company in the Stock Exchange list is now before the committee. Owing to the delay in the winding-up of the vendor companies, mainly caused by the protracted arbitration in which one of them was engaged at the time of purchase, a final settlement with them had not been effected before the close of the first financial year of this company. These difficulties have since been removed, and the directors daily expect to have the quotation granted. The sum of £75,000 which, as stated in the prospectus, Woodhouse and Rawson, Limited, was to lodge with this company as a guarantee fund for the payment of a minimum dividend of 15 per cent. per annum for the first three years, has been duly received.

The shareholders will doubtless approve of the formation of an *employés* pension fund, which will tend to the retention of those employed by the company, by requiring faithful services when age, failing health, or other causes necessitate their temporary or permanent withdrawal from the company's employ. The amount proposed to be placed to the credit of this fund, though comparatively small for the purpose intended, will form a nucleus to which in future, as the company's success is consolidated, larger sums may be allocated. A resolution to give effect to this proposal will be submitted to the meeting. The directors feel that the shareholders owe a great deal to the various members of the staff for devoted services rendered, regardless of personal comfort and hours of labour, and especially to the managing director, Mr. F. L. Rawson, to whose zeal, enterprise and judgment the results obtained in this the first year of the company's operations are mainly due. By the articles of association two directors retire. The two who retire are Lord Aberdare and Sir Rawson W. Rawson; the latter, being eligible, offers himself for re-election; the

former from impaired health and enforced absence from London, does not offer himself for re-election. In his place the directors propose, with the approval of the shareholders, to elect the Right Hon. Sir Edward Thornton, G.C.B. The auditors, Messrs. Pixley and Co., retire according to the articles, and offer themselves for re-election. In conclusion the directors congratulate the shareholders on the position and prospects of the company.

### The International Okonite Company, Limited.

Mr. SAMUEL POPE, Q.C., presided at the statutory meeting held at the Cannon Street Hotel yesterday, and after explaining the object of statutory meetings, went on to say that the company's articles of association provided that the first general meeting should be held within the statutory period of four months. The board, therefore, thought it desirable not to treat this meeting as a purely statutory one, but that the directors should meet the desire of many of the shareholders by stating exactly what had been done since they came into office, and the prospects of future development. The company's capital had originally been fixed at £440,000, divided into £170,000 of £10 preference shares, £170,000 of £10 ordinary, and £100,000 of £100 debentures. Of that amount, £113,330 had been paid to the vendors as founders' shares, as well as £33,300 of debentures. That left £226,670 of preference and ordinary shares to be allotted to the various applicants. Of that £226,670, the whole had been fully subscribed, without a single share having been underwritten. Of the debentures, out of £66,600 (the balance of the £100,000, after deducting the £33,300 to be allotted to the vendors), £51,100 had been taken up, leaving a balance of £15,000, the only balance unallotted of the entire capital, which it was the directors' intention not to allot until they required the money. The company's capital account was therefore summed up in the description that "the whole of the capital has been subscribed for and allotted," with the exception of £15,000 worth of debentures which they did not require to allot. The company's managing director and Mr. Connolly, the works manager, had visited the United States since the company's incorporation for the purpose of examining into the business and working of the factory at Passaic, New Jersey, and the special processes carried on there for the purpose of working similar plant at the company's Manchester works. The managing director had returned, Mr. Connolly was on his way home. The former reported, and the speaker believed Mr. Connolly agreed with him, that the works were in first class order, well organised, admirably arranged and fully occupied. Assuming the turn-out for 1887 as the unit 100, then the turn-out in 1888 represented 164; in 1889, 224; and in 1890, so far, the satisfactory figure of 450. In other words, the investigation had shown that the output at the American works had become four-and-a-half times what it was in 1887. In addition to the founders' shares named in the prospectus, the directors who formed the American committee had subscribed for considerably over £60,000 in shares, and paid for them in the ordinary way. The title to the American factory had been thoroughly examined and approved by the solicitors, Messrs. Davies, Short and Townsend, of New York. The whole of the purchase money had been paid, and the property in America had been invested in the Central Trust Company of New York, as trustees for the debenture holders. From personal inspection the company's managers reported themselves satisfied that the business was a sound and lucrative one with every prospect of a large and continuous increase; and that there was an immense advantage in having a factory both at New York and Manchester. With regard to the Manchester works, the business had been taken over and paid for, and the company had since acquired a plot of vacant land of about an acre, bounded on one side by the company's own factory, on another by the Rochdale Canal, and on the other two sides by good roads. On this they were actively working an improved fireproof factory for the manufacture of the company's specialité of high-class okonite wires and cables, and the necessary machinery was well in hand. The works were in full swing manufacturing the various classes of insulated wires, and orders were coming in most satisfactorily. Messrs. Shaw and Connolly had agreed to serve the company for a term of years, and, as both gentlemen had technical and business knowledge second to none in the manufacture of insulated wire, the directors had every reason to anticipate that, with the capital at their command, the English business would soon rival, if it did not exceed, the American. Certain statements as to the profits of the year had been made in the prospectus, and some shareholders had questioned the profits for 1889 and 1890 of Shaw and Connolly (which, the meeting would remember, had been taken as estimated, and not as ascertained), and also the profits of 1890 of the old Okonite Company, these profits not having been ascertained by a competent accountant at the date of the prospectus. However, the directors were now in possession of Messrs. Price and Waterhouse's report and statement, which showed the statements in the prospectus to be well under the actually ascertained amount. With regard, however, to the profits of 1890 of the old company in America, the directors had not yet received Messrs. Price and Waterhouse's certificate. The directors had cabled to New York for the most recent information as to the progress of the audit, for of course it was desirable to know as far as possible the actual facts with regard to the property acquired; and they had received from the New York office, under date September 26th, a letter which stated that the books were not quite closed, but that approximately it

was thought that the profits would be considerably larger than the prospectus claimed they would be. The actual result had since been cabled for, but the directors had not yet received the certificate. However, from what the general manager said, he (the speaker) did not doubt that the statements referred to would be abundantly justified by the facts. Of course the directors could have no great experience in the management of the concern during that short period in office, but he thought he might say that the view which his colleagues, and which he himself would desire to see carried out, would be to manage the concern with an eye to making it a substantial commercial undertaking, and not with a view merely to create a temporary fictitious value in the shares of the company. During the last three years of the Okonite Company's working they had never had returned to them a single yard of okonite wire as being of defective insulation. The whole of the wires were guaranteed to a standard far in excess of the working requirements, and were fully tested 100 per cent. over the company's guarantee before leaving the works. The same system would be adopted in England, as, although it tended to slightly increase the cost of production, it was important that their electrical insulated conductors should be of a high class, and absolutely reliable. The scrip certificates had been issued, and application had been made to the Stock Exchange for a special settlement and quotation in the official list. As showing how active the English business of the company was, the speaker produced an order from an English firm for 135,000 feet of okonite wire.

After several shareholders had expressed their satisfaction with the statements just made, an extraordinary general meeting was held, as announced, and the following resolution, which, the chairman explained, was intended to make certain minor alterations in the articles of association, which had been called for by the Stock Exchange, was passed, and the proceedings terminated.

**Resolution.**—"That the articles of association of the company be altered in the following manner:—

"(a) In clause 35, that the portion of the clause following the words 'provided that' be struck out and the following inserted: 'The funds of the company shall not be expended in the purchase of or lent upon the security of its own shares.'

"(b) In clause 72, that the following words be added at the end of the clause: 'And, unless he shall do so, he shall be deemed to have agreed to take the said shares from the company, and the same shall be forthwith allotted to him accordingly.'

"(c) In clause 116, that the following words be added at the end of the clause: 'And a copy of such balance sheet shall be posted to each member at his registered address at least eight days before such ordinary general meeting.'"

### Brazilian Submarine Telegraph Company, Limited.

—The accounts, subject to audit, show a profit sufficient to enable the directors to recommend a final dividend of 3s. per share, making, with previous distributions, a total dividend of 6 per cent. for the year ended 30th June, 1890, and also the payment of a bonus of 3s. per share, both free of income tax, which, together, will amount to £39,000, being a distribution in the aggregate of 7½ per cent. for the past year, leaving a balance of £42,416 18s. 1d., of which amount £40,000 has been placed to the reserve fund, increasing that fund to £352,626 2s. 11d., and £2,416 16s. 1d. carried forward.

**A Franco-Russian Company** is about to organise a new telegraphic agency in Servia and the other Balkan countries, the Servian Government having declined to renew its connection with the Vienna Correspondence Bureau.

**The Telephone Company of Austria, Limited**, notifies that the usual half-yearly dividend to the 30th ult. on the preference shares, at the rate of 6 per cent. per annum, has been declared by the board.

**Reuter's Telegram Company, Limited.**—The directors have declared an interim dividend at the rate of 5 per cent. per annum, free of income tax, for the half year ending the 30th June last.

### TRAFFIC RECEIPTS.

The Brazilian Submarine Telegraph Company, Limited. The traffic receipts for the week ending October 3rd, were £5,323.

The Cuba Submarine Telegraph Company, Limited. The receipts for the month of September were £3,000, as compared with £2,372 in the corresponding month of last year. The receipts for the month of June, estimated at £3,500, realised £3,324.

The Direct Spanish Telegraph Company, Limited. The estimated receipts for the month of September were £2,526, against £2,159 in the corresponding period of last year.

The Great Northern Telegraph Company, Limited. The receipts for the month of September amounted to £25,500; 1st January—30th September 1890, £108,600; corresponding months 1889, £208,200; do. 1888, £202,900.

West India and Panama Telegraph Company, Limited. The estimated traffic receipts for the half month ended September 30th, show an increase of £187 as compared with the corresponding period.

The Western and Brazilian Telegraph Company, Limited. The receipts for the week ending October 3rd, after deducting the fifth of the gross receipts payable to the London Platino-Brazilian Telegraph Company, Limited, were £4,163.

THE ELECTRO-MAGNET.\*

By Prof. SILVANUS P. THOMPSON, D.Sc., B.A., M.I.E.E.

(Continued from page 407.)

HYSTERESIS.

I have already drawn attention to the difference between the ascending and descending curves of magnetisation, and may now point out that this is a part of a set of general phenomena of residual effects. The best known of these effects is, of course, the existence in some kinds of iron, and notably in steel, of a remanent or sub-permanent magnetisation after the magnetising force has been entirely removed. To this retardation of effects behind the causes that produce them the name of "hysteresis" has been given by Prof. Ewing. If a piece of iron is subjected to a magnetising force which increases to a maximum, then is decreased down to zero, then reversed and carried to a negative maximum, then decreased again to zero, and so carried round an entire cycle of magnetic operations, it is observed that the curves of magnetisation form a closed area similar in general to those shown in fig. 21. This closed area represents the work which has been

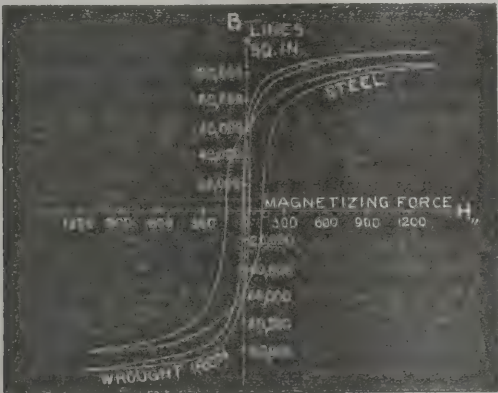

FIG. 21.—CURVES OF HYSTERESIS.

wasted or dissipated in subjecting the iron to these alternate magnetising forces. In very soft iron, where the ascending and descending curves are close together, the enclosed area is small; and, as a matter of fact, very little energy is dissipated in a cycle of magnetic operations. On the other hand, with hard iron, and particularly with steel, there is a great width between the curves, and there is great waste of energy. Hysteresis may be regarded as a sort of internal or molecular magnetic friction, by reason of which alternate magnetisations cause the iron to grow hot. Hence the importance of understanding this curious effect, in view of the construction of electromagnets that are to be used with rapidly alternating currents. The following figures of Table V. give the number of watts (1 watt =  $\frac{1}{746}$  of a horse-power) wasted by hysteresis in well-laminated soft wrought iron when subjected to a succession of rapid cycles of magnetisation:—

TABLE V.—WASTE OF POWER BY HYSTERESIS.

B	B <sub>r</sub>	Watts wasted per cubic foot at 10 cycles per second.	Watts wasted per cubic foot at 100 cycles per second.
4,000	25,800	40	400
5,000	32,250	57.5	575
6,000	38,700	75	750
7,000	45,150	92.5	925
8,000	51,600	111	1,110
10,000	64,500	156	1,560
12,000	77,400	206	2,060
14,000	90,300	262	2,620
16,000	103,200	324	3,240
17,000	109,650	394	3,940
18,000	116,100	487	4,870

It will be noted that the waste of energy increases as the magnetisation is pushed higher and higher in a disproportionate degree, the waste when B is 18,000 being six times that when B is 6,000. In the case of hard iron or of steel the heat waste would be far greater. Another kind of after effect was discovered by Ewing, and named by him "viscous hysteresis." This is the name given to the gradual creeping up of the magnetisation when a magnetic force is applied with absolute steadiness to a piece of iron. This

gradual creeping up may go on for half-an-hour or more and amount to several per cent. of the total magnetisation. Another important matter is that all such actions as hammering, rolling, twisting, and the like, impair the magnetic quality of annealed soft iron. Annealed wrought iron which has never been touched by a tool shows hardly any trace of residual magnetisation, even after the application of magnetic forces. But the touch of the file will at once spoil it. Sturgeon pointed out the great importance of this point. In the specification for tenders for instruments for the British Postal Telegraphs, it is laid down as a condition to be observed by the constructor, that the cores must not be filed after being annealed. The continual hammering of the armature of an electro-magnet against the poles may in time produce a similar effect.

FALLACIES AND FACTS ABOUT ELECTRO-MAGNETS.

I will conclude this lecture by stating a few of the fallacies that are current about electro-magnets and will add to them a few facts, some of which seem paradoxical. The refutation of the fallacies and the explanation of the facts will come in due course.

*Fallacies.*—The attraction of an electro-magnet for its armature varies inversely, as the square of its distance from the poles. The outer windings of an electro-magnet are necessarily less effective than those that are close to the iron.

Hollow iron cores are as good as solid cores of the same size. Pole pieces add to the lifting power of an electro-magnet. It hurts an electromagnet (or, for that matter, a steel magnet) to pull off the keeper suddenly. [It is the sudden slamming on that in reality hurts it.] The resistance of the coil of an electro-magnet ought to be equal to the resistance of the battery. A coil wound left-handedly magnetises a magnet differently from a coil wound right-handedly. [It is not a question of winding of coil but of circulation of current.] Thick-wire electro-magnets are less powerful than thin-wire electro-magnets. A badly insulated electro-magnet is more powerful than one that is well insulated. A square iron core is less powerful (as Dal Negro says, eighteen fold!) than a round core of equal weight. The attraction of an electro-magnet for its keeper is necessarily less strong (one-third according to Du Moncel) sideways than when the keeper is in front of the poles. Putting a tube of iron outside the coils of an electro-magnet makes it attract a distant armature more powerfully.

*Facts.*—A bar electro-magnet with a convex pole holds on tighter to a flat-ended armature than one with a flat pole does. A thin round disc of iron laid upon the flat round end of an electro-magnet (the pole end being slightly larger than the disc) the disc is not attracted, and will not stick on, even if laid down quite centrally. If a flat armature of iron be presented to the poles of a horse-shoe electro-magnet the attraction at a short distance is greater, if the armature is presented flankways, than if it is presented edgewise. On the contrary, the tractive force in contact is greater edgewise than flankways. Electro-magnets with long limbs are practically no better than those with short limbs for sticking on to masses of iron.

LECTURE II.—DELIVERED JANUARY 27TH, 1890.

General Principles of Design and Construction.—Principle of the Magnetic Circuit.

To-night we have to discuss the law of the magnetic circuit in its application to the electro-magnet, and in particular to dwell upon some experimental results which have been obtained from time to time by different authorities as to the relation between the construction of the various parts of an electro-magnet, and the effect of that construction on its performance. We have to deal not only with the size, section, length, and material of the iron cores, and of the armatures of iron, but we have to consider also the winding of the upper coil, and its form; and we have to speak in particular about the way in which the shaping of the core and of the armature affects the performance of the electro-magnet in acting on its armature, whether in contact or at a distance. But before we enter on the last more difficult part of the subject, we will deal solely and exclusively with the law of force of the magnet upon its armature when the two are in contact with one another; in other words, with the law of traction.

I alluded in a historical manner in my first lecture to the principle of the magnetic circuit, telling you how the idea had gradually grown up, perforce, from a consideration of the facts. The law of the magnetic circuit was, however, first thrown into shape in 1873 by Prof. Rowland, of Baltimore. He pointed out that if you consider any simple case, and find (as electricians do for the electric circuit) an expression for the magnetising force which tends to drive the magnetism round the circuit, and divide that by the resistance to magnetisation reckoned also all round the circuit, the quotient of those two gives you the total amount of flow or flux of magnetism. That is to say, one may calculate the quantity of magnetism that passes in that way round the magnetic circuit in exactly the same way as one calculates the strength of the electric current by the law of Ohm. Rowland, indeed, went a great deal further than this, for he applied this very calculation to the experiments made by Joule more than 30

\* Cantor Lecture. Delivered before the Society of Arts, January 20th, 1890.

years before, and from those experiments deduced the degree of magnetisation to which Joule had driven the iron of his magnets, and by inference obtained the amount of current that he had been causing to circulate. Now this law requires to be written out in a form that can be used for future calculation. To put it in words without any symbols, we must first reckon out from the number of turns of wire in the coil, and the number of amperes of current which circulates in them, the whole *magneto-motive force*—the whole of that which tends to drive magnetism along the piece of iron—for it is, in fact, proportional to the strength of the current, and the number of times it circulates. Next we must ascertain the resistance which the magnetic circuit offers to the passage of the magnetic lines. I here avowedly use Joule's own expression, which was afterwards adopted by Rowland, and, for short, so as to avoid having four words, we may simply call it the *magnetic resistance*. Mr. Heaviside has suggested as an advisable alternative term, *magnetic reluctance*, in order that we may not confuse the resistance to magnetism in the magnetic circuit with the resistance to the flow of current in an electric circuit. However, we need not quarrel about terms; magnetic reluctance is sufficiently expressive. Then having found these two, the quotient of them gives us a number representing—I must not call it the strength of the magnetic current—I will call it simply the quantity or number of magnetic lines which flow round the circuit; or if we could adopt a term which is used on the Continent, we might call it simply the *magnetic flux*: the flux of magnetism being the analogue of the flow of electricity in the electric law. The law of the magnetic circuit may then be stated as follows:—

$$\text{Magnetic flux} = \frac{\text{magneto-motive force}}{\text{reluctance}}.$$

However, it is more convenient to deal with these matters in symbols, and therefore the symbols which I use, and have long been using, ought to be explained to you. For the number of spirals in a winding I use the letter  $s$ ; for the strength of current, or number of amperes, the letter  $i$ ; for the length of a bar, or core, I am going to use the letter  $l$ ; for the area of cross section, the letter  $A$ ; for the permeability of the iron which we discussed in the last lecture, the Greek symbol  $\mu$ ; and for the total magnetic flux, the number of magnetic lines, I use the letter  $N$ . Then our law becomes as follows:—

$$\text{Magneto-motive force} = \frac{4 \pi s i}{10};$$

$$\text{Magnetic reluctance} = \frac{l}{A \mu};$$

$$\text{Magnetic flux} \dots N = \frac{\frac{4 \pi s i}{10}}{\frac{l}{A \mu}} = \frac{4 \pi s i A \mu}{10 l}.$$

If we take the number of spirals and multiply by the number of amperes of current, so as to get the whole amount of circulation of electric current expressed in so many ampere-turns, and multiply by  $4\pi$ , and divide by ten, in order to get the proper unit (that is to say, multiply it by 1.257), that gives us the magneto-motive force. For magnetic reluctance, calculate out the reluctance exactly as you would the resistance of an electric conductor to the flow of electricity, or the resistance of a conductor of heat to the flow of heat; it will be proportionate to the length, inversely proportional to the cross section, and inversely proportional to the conductivity, or, in the present case, to the magnetic permeability. Now if the circuit is a simple one, we may simply write down here the length, and divide it by the area of the cross section and the permeability, and so find the value of the reluctance. But if the circuit be not a simple one, if you have not a simple ring of iron of equal section all round, it is necessary to consider the circuit in pieces as you would an electric circuit, ascertaining separately the reluctance of the separate parts, and adding all together. As there may be a number of such terms to be added together, I have prefixed the expression for the magnetic reluctance by the sign  $\Sigma$  of summation. But it does not by any means follow because we can write a thing down as simply as that, that the calculation out of it will be a very simple matter. In the case of magnetic lines, we are quite unable to do as one does with electric currents to insulate the flow. An electric current can be confined (provided we do not put it in at 10,000 volts pressure, or anything much bigger than that) to a copper conductor by an adequate layer of adequately strong—and I use the word "strong" both in a mechanical and electrical sense—of adequately strong insulating material. There are materials whose conductivity for electricity, as compared with copper, may be regarded perhaps as millions of millions of millions of times less; that is to say, they are practically perfect insulators. There are no such things for magnetism. The most highly insulating substance we know of for magnetism is certainly not 10,000 times less permeable to magnetism than the most highly magnetisable substance we know of, namely, iron in its best condition; and when one deals with electro-magnets where curved portions of iron are surrounded with copper, or with air, or other insulating material, one is dealing with substances whose permeability, instead of being infinitely small, compared with that of iron, is quite considerable. We have to deal mainly with iron when it has been well magnetised. Its permeability, compared with air, is from 1,000 to 100 roughly; that is to say, the permeability of air compared with the iron is not less than  $\frac{1}{100}$ th to  $\frac{1}{1000}$ th part. That means that it is quite possible to have a very considerable leakage of mag-

netic lines from iron into air occurring to complicate one's calculations, and prevent an accurate estimate being made of the true magnetic reluctance of any part of the circuit. Suppose, however, that we have got over all these difficulties, and made our calculations of the magnetic reluctance; then dividing the magneto-motive force by the reluctance gives us the whole number of magnetic lines.

There, then, is in its elementary form the law of the magnetic circuit stated exactly as Ohm's law is stated for electric circuits. But as a general rule one requires this magnetic law for certain applications, in which the problem is not to calculate from those two quantities what the total of magnetic lines will be. In most of the cases a rule is wanted for the purpose of calculating back. You want to know how to build a magnet so as to give you the requisite number of magnetic lines. You start by assuming that you need to have so many magnetic lines, and you require to know what magnetic reluctance there will be, and how much magneto-motive force will be needed. Well, that is a matter precisely analogous to those which every electrician comes across. He does not always want to use Ohm's law in the way in which it is commonly stated, to calculate the current from the electromotive force and the resistance; he often wants to calculate what is the electromotive force which will send a given current through a known resistance. And so do we. Our main consideration to-night will be devoted to the question how many ampere turns of current circulation must be provided in order to drive the required quantity of magnetism through any given magnetic reluctance. Therefore, we will state our law a little differently. What we want to calculate out is the number of ampere turns required. When once we have got that, it is easy to say what the copper wire must consist of; what sort of wire, and how much of it. Turning then to our algebraic rule, we must transform it, so as to get all the other things beside the ampere turns, to the other side of the equation. So we write the formula:—

$$s i = \frac{N \cdot \Sigma \frac{l}{A \mu}}{1.257}$$

We shall have then the ampere turns equal to the number of magnetic lines we are going to force round the circuit multiplied by the sum of the magnetic reluctances divided by 1.257. Now, this number, 1.257, is the constant that comes in when the length,  $l$ , is expressed in centimetres, the area in square centimetres, and the permeability in the usual numbers. Many persons, unfortunately—I say so advisedly, because of the waste of brain labour that they have been compelled to go through—prefer to work in inches and pounds and feet. They have, in fact, had to learn tables instead of acquiring them naturally without any learning. If the lengths be specified in inches, and areas in square inches, then the constant is a little different. The constant in that case, for inches and square inch measures, is 0.3132, so that the formula becomes:—

$$s i = N \times \Sigma \frac{l''}{A'' \mu} \times 0.3132.$$

Here it is convenient to leave the law of the magnetic circuit, and come back to it from time to time as we require. What I want to point out before I go to any of the applications is, that with the guidance provided by this law, one after another the various points that come under review can be arranged and explained, and that there does not now remain—if one applies this law with judgment—a single fact about electro-magnets which is either anomalous or paradoxical. Paradoxical some things may seem in form, but they all reduce to what is perfectly rational when one has a guiding principle of this kind to tell you how much magnetisation you will get under given circumstances, or to tell you how much magnetising power you require in order to get a given quantity of magnetisation. I am using the word "magnetisation" there in the popular sense, not in the narrow mathematical sense in which it has sometimes been used (*i.e.*, for the magnetic moment per unit cube of the material). I am using it simply to express the fact that the iron or air, or whatever it may be, has been subjected to the process which results in there being magnetic lines of force induced through it.

Now let us apply this law of magnetic circuit, in the first place, to the traction, that is to say, the lifting power of electro-magnets. The law of traction I assumed in my last lecture, for I made it the basis of a method of measuring the amount of permeability. The law of magnetic traction was stated once for all by Maxwell, in his great treatise, and it is as follows:—

$$P \text{ (dynes)} = \frac{B^2 A}{8 \pi},$$

where  $A$  is the area in square centimetres. This becomes

$$P \text{ (grammes)} = \frac{B^2 A}{8 \pi \times 981}.$$

That is, the pull in grammes per square centimetre is equal to the square of the magnetic induction,  $B$  (being the number of magnetic lines to the square centimetre), divided by  $8 \pi$ , and divided also by 981. To bring grammes into pounds you divide by 453.6; so that the formula then becomes:—

$$P \text{ (lbs.)} = \frac{B^2 A}{11,183,000};$$

or if square inch measures are used:—

$$P \text{ (lbs.)} = \frac{B^2 A''}{72,134,000}.$$

To save future trouble we will now calculate out from the law of traction the following table, in which the traction in grammes per square centimetre or in pounds per square inch, is set down opposite the corresponding value of *B*.

TABLE VI.—MAGNETISATION AND MAGNETIC TRACTION.

<i>B</i> lines per square centimetre.	<i>B</i> lines per square inch.	Dynes per square centimetre.	Grammes per square centimetre.	Kilogrammes per square centimetre.	Pounds per square inch.
1,000	6,450	39,790	40.56	.0456	.577
2,000	12,900	159,200	162.3	.1623	2.308
3,000	19,350	358,100	365.1	.3651	5.190
4,000	25,800	636,600	648.9	.6489	9.228
5,000	32,250	994,700	1,014	1.014	14.39
6,000	38,700	1,432,000	1,460	1.460	20.75
7,000	45,150	1,950,000	1,987	1.987	28.26
8,000	51,600	2,547,000	2,596	2.596	36.95
9,000	58,050	3,223,000	3,286	3.286	46.72
10,000	64,500	3,979,000	4,056	4.056	57.68
11,000	70,950	4,815,000	4,907	4.907	69.77
12,000	77,400	5,730,000	5,841	5.841	83.07
13,000	83,850	6,725,000	6,855	6.855	97.47
14,000	90,300	7,800,000	7,550	7.550	113.1
15,000	96,750	8,953,000	9,124	9.124	129.7
16,000	103,200	10,170,000	10,390	10.39	147.7
17,000	109,650	11,500,000	11,720	11.72	166.6
18,000	116,100	12,890,000	13,140	13.14	186.8
19,000	122,550	14,360,000	14,630	14.63	208.1
20,000	129,000	15,920,000	16,230	16.23	230.8

This simple statement of the law of traction assumes that the distribution of the magnetic lines is uniform all over the area we are considering; and that, unfortunately, is not always the case. When the distribution is not uniform, then the mean value of the squares becomes greater than the square of the mean value, and consequently the pull of the magnet at its end face may, under certain circumstances, become greater than the calculation would lead you to expect—greater than the average of *B* would lead you to suppose. If the distribution is not uniform over the area of contact, then the accurate expression for the tractive force (in dynes) will be

$$P = \frac{I}{8 \pi} \int B^2 dA,$$

the integration being taken over the whole area of contact.

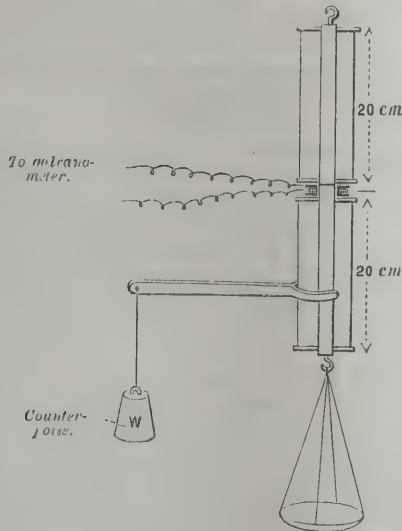

FIG. 22.—BOSQUET'S VERIFICATION OF THE LAW OF TRACTION.

This law of traction has been verified by experiment. The most conclusive investigations were made about 1886 by Mr. R. H. M. Boscquet, of Oxford, whose apparatus is depicted in fig. 22. He took two cores of iron, well faced, and surrounded them both by magnetising coils, fastened the upper one rigidly, and suspended the other one on a lever with a counterpoise weight. To the lower end of this core he hung a scale pan, and measured the traction of one upon the other when a known current was circulating a known number of times round the coil. At the same time he placed an exploring coil round the joint, that exploring coil being connected, in the manner with which we were experimenting last week, with a ballistic galvanometer; so that at the moment when the two surfaces parted company, or at the moment when the magnetisation was released by stopping the magnetising current, the galvanometer indication enabled him to say exactly how many magnetic lines went through

that exploring coil. So that, knowing the area, you could calculate the number per square centimetre, and you could therefore compare *B*<sup>2</sup> with the pull per square centimetre obtained directly on the scale-pan. Boscquet found that even when the surfaces were not absolutely perfectly faced the correspondence was very close indeed, not varying by more than 1 or 2 per cent. except with small magnetising forces, say forces less than 5 C.G.S. units. When one knows how irregular the behaviour of iron is when the magnetising forces are so small as this, one is not astonished to find a lack of proportionality. The correspondence was, however, sufficiently exact to say that the experiments verified the law of traction, that the pull is proportional to the square of the magnetic induction through the area, and integrated over that area.

(To be continued.)

14634. "Improved apparatus for electric light signalling." E. F. INGLEFIELD. Dated September 16. (Complete.)

14666. "Improvements in electric switches." J. CHARTERS. Dated September 17.

14679. "Improvements in electrical alarm apparatus for shops, stores, and other purposes." W. WILKINSON and W. A. SYKES. Dated September 17.

14686. "Improvements relating to the preparation or treatment of carbons for electric lamps or lighting apparatus." W. R. LAKE. (Communicated by Lacombe & Co., France.) Dated September 17.

14696. "Improved telegraphic relay." J. P. BAYLY. (Communicated by J. M. Treber, United States.) Dated September 17.

14698. "Improvements in conductors for the distribution of electrical energy, and in apparatus connected therewith." R. E. B. CROMPTON and W. A. CHAMEN. Dated September 17.

14748. "Improvements in apparatus for electrically giving alarm from letter plates, post boxes, and other purposes." P. WILLIAMS. Dated September 18.

14776. "An improved process and means for the electro-deposition of metals." C. T. J. VAUTIN. Dated September 18.

14807. "An improvement in the supply of electricity in medical cases." J. GNEZDA. Dated September 19.

14817. "Improvements in and relating to the distribution of electrical energy." R. KENNEDY. Dated September 19. (Complete.)

14830. "Improved means of accommodating electric wires in buildings." F. WALTON. Dated September 19.

## ABSTRACTS

### OF PUBLISHED SPECIFICATIONS, 1889.

6544. "Improvements relating to electric incandescence lamps." A. A. GOLDSTON. Dated April 16. 8d. The object of the invention is to provide such lamps with improved cut-outs, adapted to operate automatically when the carbons or light-giving conductors become destroyed. 5 claims.

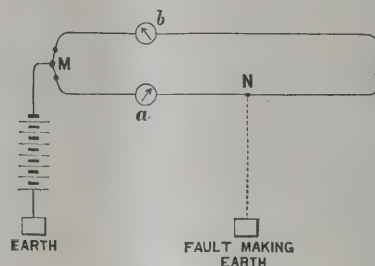

6578. "Improvements in arc lamps." G. HOOKHAM. Dated April 17. 8d. The feed mechanism is actuated by the weight of the upper carbon and the carbon holder. The descent of this weight is retarded by the eddy currents generated in a Foucault disc. 1 claim.

6675. "Improvements in electrically-driven fans." H. G. WATTEL. Dated April 18. 6d. The inventor converts the rim of the fan into the armature of an electro-dynamic machine, or he applies the ring armature of such a machine to the periphery of the fan, and converts the fixed framing within or against which the fan works into field electro-magnets, or he applies such field magnets to the framing. 2 claims.

## A SPEEDY METHOD OF LOCALISING DEFECTS IN AN ELECTRIC LIGHTING CIRCUIT.

THIS is described by M. Henri Wilbrant (*La Lumière Electrique*), who recommends it for its simplicity. An earth connection had formed in the negative conductor of a double line, the latter being composed of two parallel and identical protected cables laid in the clay. The following diagram indicates the way in which the defect was localised:—An ampèremeter is attached to each conductor where the line commences, and both conductors are united together to a powerful battery of accumulators. At the end of the line the conductors are looped together. The battery being connected to the earth at its other extremity the current is closed by the defect and by the conductors forming the shunts,  $M b N$ , and  $M a N$ . Measures have been taken for obtaining an intensity of current that will render the reading of the ampèremeter an easy matter. The readings,  $a$  and  $b$ , are inversely proportional to the resistances of the circuits in which the instruments have been inserted, and, as the conductor cables are

identical, the resistances are directly proportional to the lengths in metres. It is as well to take into account any resistances from accessory loose cables in effecting the junctions with the ampèremeter and the battery.

Let  $x$  represent the length in metres from the commencement of the cable to the defect (shunt  $M a N$ );  $L$  the length in metres of the two cables (this length having been previously ascertained), and  $a$  and  $b$  the number of the ampères indicated by the instruments, the ordinary calculation of the ramified circuits is:—

$$x = \frac{b L}{a + b}$$

In applying this method to the total length of a 900 metres line, an approximation was obtained of close upon 5 metres, the difference being attributable to difficulty in reading from ampèremeters of the ordinary type.

## COMMUNICATIONS FROM AUSTRIA-HUNGARY.

[FROM A CORRESPONDENT.]

THE Buda-Pest electric town tramline makes constantly so satisfactory advances, that it already appears necessary to enlarge the central current installation of this line. On behalf of the undertaking of the town line which is applying for the concession of the execution of this extension, its necessity is urged along with the establishment of a new line, on account of the increased traffic on the most important lines. The concession will, without doubt, be granted.

At the Innsbruck electric central station, an interesting case has occurred. A spider was climbing, during the work, on one of the lightning protectors, and occasioned an earth connection, in consequence of which an induction bobbin was damaged by breaking the insulation. In order to prevent similar occurrences for the future, the lightning protector plates are closed up in glass boxes. The spider itself has paid with its life for its unwarranted intrusion into the primary circuit of 2,000 volts.

The Vienna Electric Company (not to be confounded with the International Electric Company, also established in Vienna), has erected in the Neubad Gasse an electric central station, with the use of the five-lead system. For employing this system in one of the most densely-populated quarters of the city, the company had to erect electrical works which naturally occasioned serious annoyance to the inhabitants, and, in consequence, an endless succession of law suits. The peculiar situation in which the company is now placed is illustrated by the following notice from the Vienna *Extra-blatt*. Says this paper: At last the thoroughfare through the Neubadgasse into the Naglergasse, after being closed for three years, is reopened. Still the process between the inhabitants and the electric company is not yet decided. The inhabitants, especially Prince Esterhazy (represented by Dr. Lichtenstern), Herr Wieser, of the Neubad Hotel, and Herr Haag, of the Hotel Müller (represented by Dr. Peiez), and the Knight von Weissenfeld (represented by Dr. Ziegler) have entered actions against the company, as the powerful machinery disturbs the quietness and causes the walls to vibrate. The company has been

ordered to construct the machinery so as to abate the nuisance. But it has latterly appealed against this decision, and there is now a perfect complication of appeals, protests, decrees, and decisions. One night a 400 horse-power engine at the central station was set in action, when confusion at once arose in the adjoining houses, the walls trembled, the windows rattled, and Prince Esterhazy leaped out of bed in dismay. Count Kielmansegg the "Statthalter," a municipal official of higher rank than a mayor, at once visited the Prince's palace and the hotels Müller and Neubad, and convinced himself of the reality and the nature of the disturbance.

### THE SEVILLE CENTRAL STATION.

A CENTRAL electric light station has been erected in the Calla de Las Mozas, Seville, and is described in a newspaper published in that town. The boilers comprise six of the well-known Belleville type, and four vertical compound Offman steam engines. Four compound dynamos of the Brown type are installed, each having an output of 480 ampères, at a difference of potential of 110 volts. These dynamos and the engines were made by the well-known Oerlikon Engineering Works, near Zürich, whilst the regulating apparatus was furnished by Messrs. Woodhouse and Rawson United.

The distribution of current is effected by means of mains laid underground. These mains consist of copper wires insulated by vulcanised rubber, and then encircled with leaden tubes, and laid in iron pipes, which form the conduit. Current is obtainable both day and night. The incandescent lamps employed range from 10 to 1,000 candle-power, and the arc lamps from 500 to 1,000 C.P. The price charged for current compares very favourably with that of gas, even when the cost of wiring is considered. Already a number of subscribers has been obtained, and, notwithstanding the local opposition, it is expected that the station will become a commercial success, and probably be the forerunner of several others in Andalusia.

### CONFERENCE OF POSTAL TELEGRAPH CLERKS.

A SPECIAL conference of postal telegraph clerks will be held in Liverpool to-morrow, when the features of the recent revision of their status will form the chief subject of discussion. The importance of such a meeting can scarcely be exaggerated when it is remembered that the delegates attending represent the whole of the members of the postal telegraph staff throughout the United Kingdom, this section of the public service alone numbering, we believe, upwards of 10,000 members.

That the deliberations of this assembly will be followed with peculiar interest and concern by all parties throughout what is termed "the service" goes without saying, and to many who are not telegraph clerks, but who trace the course of current events, the reintroduction of that outcome of the "benevolent disposition" of the Postmaster-General and his administrators, "the official reporter" will revive the recently-discussed topic of the right to "free public meeting."

Many of our readers will remember the restrictions placed this year on all sections of Post-office *employés* holding such meetings, their general and almost unqualified condemnation by the press, and their plausible interpretation by the Postmaster-General in the House of Commons and elsewhere. General doubt was expressed as to the genuineness of the "benevolence" attending such unnecessary limitations, and it is melancholy news indeed to hear that the movement which the telegraph clerks have carried on so moderately and constitutionally has not been signalled by equal forbearance and consideration on the part of those

for whom the Postmaster-General has professed almost too much in the House of Commons. We refer now to the dismissal of a well-known and popular member of the London staff; a young man whose only faults appear to have been his manly candour and his unswerving honesty of purpose.

Elected by the staff of the Central Telegraph Department to a position on the executive committee, intelligent, enthusiastic, and, as we have already said, honest, he in some way fell foul of the higher authorities, his dismissal being due to "what he had said," though where and when the negative or positive oration which led to this result was delivered was not vouchsafed.

It is gratifying, however, to learn that a promising opening has already been found for this young man, and that he has little to regret in leaving the Telegraph Department beyond the loss of seven or eight years of underpaid service. Possibly, if he be of a thoughtful or enquiring turn of mind, he may ask, in the words of Burns—

Why was an independent wish  
E'er planted in my mind?

and, for an answer, the Postmaster-General might commend him to the same poet's lines on "The Creed of Poverty." Under the circumstances he will amply realise their point.

As might be expected, the delegates attending the conference will be asked to give utterance to an expression of sympathy with their late colleague.

It is no doubt one of the stock arguments of the Civil Service at such times, that examples must be made, and, that the line, as the hangman said, must be drawn somewhere, so we are not surprised to hear that others are under a certain degree of official displeasure. The effect of such incidents on the calm debating spirit and general character of a conference such as that under notice cannot be said to be reassuring, but we trust that in all its transactions the special conference of telegraph clerks will refrain from taking up a position which might be construed as expressive of resentment, defiance or disgust, at the same time exhibiting neither timidity nor panic, but holding steadfastly on for the recognition of those claims which are reasonable and justifiable in the general interests of all classes of postal telegraph clerks.

We have made a careful study of the new scales of pay, their methods of application, new system of sick pay, hours of duty, the matter of annual leave, and last, but not least, the vexed question of a "reasonable prospect." These important points it is our intention to discuss more fully hereafter. We find that much as has been done by the Postmaster-General and those who have been at his right hand throughout the framing of the new scheme, there still remains much to level up and much to clear away.

The substantial benefits conferred must not be lost sight of by the conference, neither should they be overrated, as some of the reforms may be said to be more apparent than real, and it will not be until July, 1891, that the general body of telegraph clerks will feel any appreciable improvement in their salaries.

It will not inspire the public with very high ideas of the way things are being administered in the telegraph service when it is known that increments were given under the new scheme at some of the provincial offices recently, and recalled in a week or two after. This may be a playful method of perpetrating a joke, but there is something very clumsy about it notwithstanding, and no one will envy the feelings of the unfortunate individuals concerned.

Whether the revision of the new scales of pay may be practicable at the present time or not we cannot say, but it is stated that they are not regarded as being entirely satisfactory, and we believe that moderate and rational methods will gain for the telegraph clerks the more equitable settlement of such minor points as appear to us to require improving. For instance, the inconsiderate system of stopping the pay of the poorer sections during absence through sickness, whilst others have gained the great boon of exemption from deduction or stoppage, will,

we think, if properly represented, be remedied. The question of annual leave will also bear remodelling, and we are hopeful that the Postmaster-General has not yet exhausted his beneficial resources; and no doubt the conference will recognise other features on which they may feel it their duty as well as their privilege to approach the Postmaster-General.

## CORRESPONDENCE.

### Alternating Current Meters.

Referring to the letter of Mr. Tesla in last week's ELECTRICAL REVIEW on the subject of alternating motors, I should feel obliged if you would allow me to modify some statements therein contained with reference to an alternating current meter devised by Messrs. Alderton, Philpott, and myself, and recently perfected by Mr. Ferranti.

In August, 1888, while experimenting with an alternating current meter made on the principle suggested by Prof. Ferraris in the spring of that year, viz., surrounding a copper cylinder, capable of rotating, by two coils at right angles to each other, through which two currents differing in phase were passed, the difference of phase being obtained by using the currents from the primary and secondary of an induction coil. I modified this arrangement by substituting Mr. Tesla's ring-shaped field with two pairs of coils wound on the quadrants, and passed through these two circuits respectively, currents from the primary and secondary of a transformer, instead of using a special two-phase generator, as employed by Mr. Tesla. Then a co-worker of mine in the same field, Mr. G. Alderton, suggested making the above ring-field act as the transformer itself by short-circuiting on themselves a few turns of copper wire in two opposite quadrants and sending an alternating current through the other quadrant's coils. This answered, but was greatly improved by making each of the two short-circuited secondaries only cover an octant instead of a quadrant, and the first meter of this form was put in the Grand Hotel at Brighton in September, 1888.

Mr. G. J. Philpott then discovered that rotation of the iron disc could be produced by placing it in the field formed of laminated iron stampings of the shape of a J, the disc being put near the curved part of the iron, and the straight part magnetised by an alternating field. We then found that the rotation was very much accelerated by putting a few short circuited turns of copper wire round part of the iron magnet which was uncovered by the exciting coil. Within a week of this improvement being made, we were naturally disappointed to find in the ELECTRICAL REVIEW that Prof. Elihu Thompson had forestalled us in some of our forms, and in enunciating the most probable cause of these rotations, namely, the gradual movement of the magnetic poles along a mass of iron in or around which secondary currents are allowed to be generated, or as Dr. Fleming happily puts it, "a gradual shifting of a magnetic pole takes place owing to the *high magnetic self-induction of the core*." I may add that Mr. Philpott found that these rotations could be observed in certain positions near a loaded transformer in which the magnetic leakage was excessive, and thus formed a rough test of the transformer's defect in this respect.

I quite think with Mr. Tesla that his latest method of obtaining rotations by magnetically screening part of the iron poles is distinct from the method mentioned above, but think he is wrong in stating that the rotation in our meter is due to the same cause as that in the Schallenberg form. There appears to be several methods of producing this valuable effect of rotation of an armature without collectors or commutators, in an alternating field, which do not necessarily all require the same explanation. For instance, I would refer your readers

to the interesting electrical apparatus devised by M. Fontevielle and described in the ELECTRICAL REVIEW in July 1880; also to the wonderfully ingenious meters devised by M. Borel and Paccaud in 1887 and patented in this country in January, 1888. Perhaps the above may show Mr. Tesla that it is quite possible for different individuals to work in this interesting field, without the fact of like results being obtained, in any way detracting from the individual merits of their labours, or that there can be only one cause for these rotations.

Arthur Wright.

October 7th, 1890.

### Telephone Induction Coils.

In your last number you have a description under this heading of an arrangement by Mr. T. D. Lockwood in which a closed magnetic circuit induction coil is used in conjunction with an ordinary open ended coil. It is not, however, of this that I wish so particularly to speak as of the editorial note appended, in which you state that you "witnessed some experiments a few years ago with coils constructed like transformers, to be used for translation purposes from a single wire to a double wire system, but the speaking results were extremely poor, though the ringing of the call bells (in the magnets principally), was all that could be desired. On the other hand it was found that when ordinary induction coils were used as translators the speaking was excellent, but the magneto bells would not ring."

Now in connection with a patent taken out in 1885 by Mr. Ferranti and myself we carried on an extended series of experiments with coils of this character, particularly with a view to their use as you describe, viz., as translators from a single to a double wire or *vice versa*, and with the intention that the call signals should be made right through both coils by induction without the intervention of any extraneous apparatus. Several curious and interesting effects were obtained exactly in accordance with theory, in fact such coils can be made to illustrate many of the laws of induction in a most pleasing and convincing manner.

The results vary in accordance with the way the coils are constructed, but it is by no means the case that when the coils are properly made the speaking results are extremely poor. In some experiments at the telegraph office on an underground wire to Gloucester Road, for which facilities were kindly afforded by Mr. Preece, the speaking through the coils best suited to the work was found to be indistinguishable from that through coils which the Post Office authorities, after many experiments, had found to give the best effects. In addition to this of course the closed circuit coils possessed the advantage that call signals could be transmitted through them, even when the resistance of the circuits was considerable.

It is true that coils can be constructed to give astonishing results when signalled through, but in which the speaking is poor, if the main line has any appreciable capacity, such a form, however, must be avoided.

I send you this note in the interest of closed circuit coils when used as translators. When used as transmitter coils they certainly do not appear to be successful, no doubt for the reason advanced by Mr. Lockwood.

The whole subject, however, demands fuller and more exact treatment than it has yet received.

G. L. Addenbrooke.

October 1st, 1890.

### Electrical Heterodoxy.

It can be easily seen there was no attempt to disguise the logomachy of my letter, the whole subject has been a contention of words ever since Benjamin Franklin enunciated the one force theory of elec-

tricity, in which positive and negative (now + and -) mean plus and minus.

But why does Mr. Johnstone take me to task over the one particular paragraph, there is not a great deal of logomachy in contending that plus and minus electrification and the quality of polarity do not necessarily force one to believe in two electricities. If plus and minus anything are not opposite and therefore polar qualities, I fail to understand what + and - mean. Had I written positive and negative electricity Mr. Johnstone's objection might be valid. I am not so sure the other paragraph would have remained unwritten had I perused Mr. Johnstone's book, it would take a lot of evidence to prove to my satisfaction that glass is porous in the sense referred to. Mr. Johnstone writes of electric matter passing through the pores of glass. What is this "electric matter"? A substance of course, or it could not be matter and what are these "particles of a current of electricity." In contending for his "electric matter" Mr. Johnstone must beware of getting logomachic, for there was a theory of an electric fluid, and I suppose fluid must be matter. I presume the test tube used by Mr. Johnstone, also the several referred to in the editorial article were (according to Mr. Johnstone) sufficiently porous to let the "electric matter" through. Notwithstanding Mr. Johnstone's theory that a Leyden jar becomes charged because of the smallness of the glass pores and therefore the above series of test tubes most unsuitable material, I fancy few experimentalists will hesitate to say the whole lot of these non-perforated porous tubes would make very fair Leyden jars.

Really there is little necessity for me to read Mr. Johnstone's book.

It would have been more to the point had Mr. Johnstone shown the apparatus illustrated in my letter *did not* tend to prove the explanation in the editorial article and also to have shown that my surmise, *re* the gas flame was incorrect.

But why this contention for electric matter, fluid or what not? When things might be simplified by the endeavour to demonstrate that electrical effects are the results of certain conditions of motion in the matter of the circuit itself, whether the effects or circuits be electric or magnetic, I have not brain power sufficient to say how and why but feel sure a future Faraday will arise and put us right in simple and truthful language.

As this logomachic correspondence can do little else than waste valuable space, it is concluded so far as I am concerned.

Henry Sutton

October 4th, 1890.

#### Fusible Cut-Outs in Armatures.

Your correspondent "E. J. M." will find his enquiry of 5th ultimo answered by referring to United States patent, No. 281,904 of July 24th, 1883, wherein I have covered the use of fusible plugs between each section of the armature and the corresponding segments of the commutator of both dynamos and motors.

J. M. McMahan.

October 2nd, 1890.

#### Reciprocating and Stationary Lines of Force.

Prof. Elihu Thomson, in his recent communication to you in your issue of September 26th, appears doubtful as to whether the lines of magnetism emanating from the axial solenoid in his new machine rotate with the revolving core and armature; and we are told "the actions would be the same whether they rotate or not." This, I think, is a somewhat hasty conclusion, even from such an authority; for if the classification of physical or magnetic actions is permissible, and, as experience teaches, desirable, then the distinction between fixed magnetism and reciprocating or vibrating mag-

netism would determine the category in which this machine should be placed: if in the induction coil class or with the Gramme or Siemens type of continuous current machines.

The former depend for their current on reciprocating lines of force intersecting an electrical conductor, while the latter produce current by the continuous movement of a conductor through fixed lines of force.

It is as well to be clear, to lay hold of the right line of thought, to see the path we are treading and whither it may lead, even though ultimate results may at present be obscured by the mists of uncertainty. It is reassuring to feel that one is on the right track.

Like a man, a dynamo has an inside and an outside. The latter may not be impressive or picturesque; but it is the inner life, the lively and conflicting forces to be seen only by the mind's eye, that makes electrical contrivances so interesting.

Logically, it would appear desirable to call all machines induction coils or transformers that depend on the reversal, variation, or cessation of magnetic force; whether these changes be brought about by an automatic contact breaker or by the mechanical rotation of masses of iron under inductive influence; the necessary periodicity of change in magnetic state being produced either electrically, by the make and break apparatus; or mechanically, by the rotation of an iron armature of a suitable shape, so as to cause a rhythmic and variable magnetic action.

It is feasible that the *result* would be the same—that is, more or less—whether the magnetism revolved or not in Prof. Thomson's alternator. But a result may be the consequence of many actions, and it is a legitimate field for enquiry to find out what these actions are.

There would seem to be much opposed or conflicting magnetism in this alternator—possibly a detail question in construction. For instance, the bobbins on the periphery of the machine are double in number to the projections of the armature; and by the continuity of the magnetic circuit, which obtains its energy from the axial solenoid, all the bobbins are in themselves more or less saturated, and all of like polarity, without reference to the armature. But as the armature can only cover half the number of bobbins, it follows that a polarity of opposite sign must necessarily be induced in every alternate bobbin not covered by the armature, and this sign would be opposed to that which it would acquire from the framework of the machine, while its direction would be at right angles to it. There are some conflicting forces here.

With reference to the distribution of the lines of magnetism in the core or axis, and in the armature itself, if the armature were a drum instead of being variable in mass, I am certain it would rotate through the magnetism the same as the core of a Gramme armature passes through the magnetism held in space by the inductive action of its field magnets. The fact of the armature being irregular in shape, or heterogeneous in mass—having regard to the space it occupies in revolving—is why I have a little doubt about its action.

It is the excitation of the solenoid that brings the magnetism into existence, and that is a fixed element. If the cause is stationary, should not the effect be stationary also? I cannot conceive magnetism to be elastic; if it were so, dynamo machines would have been an unknown commodity and an impossibility. I have written on this part of the question before in the columns of your contemporary, the *Electrician*, 1887.

Enclosed is an illustration or suggestion for an experiment which would decide the point. I have no opportunity for making it myself. On the shaft (fig. 1), each side of the armature, is a metallic band, insulated from but fixed to the shaft. A number of copper strips are in electrical communication with the bands, and go over and enclose the armature as shown, preferably placed at about the centre of each cavity of the armature. Collectors on each side. The central and exciting coil and the frame are shown in section, while the armature with the conducting strips is in perspective.

Now, if the magnetism rotates with the armature,

there should be no decisive indication of current through the collectors, because if the magnetism rotated at all, it would travel at the same speed as the armature and the conducting strips. But if the magnetic lines are stationary, then there should be unmistakable evidence of current; in fact, it would be a continuous current dynamo of its kind.

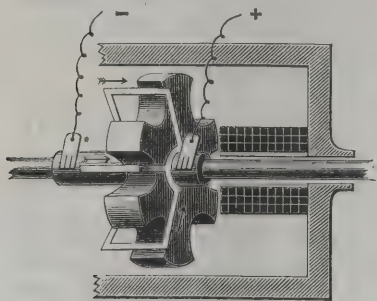

FIG. 1.

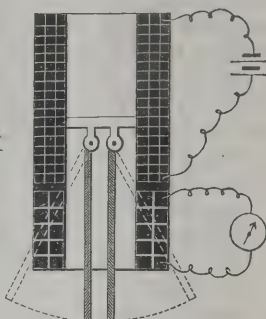

FIG. 2.

However, the immediate or direct cause of current in Prof. Thomson's machine may be explained on the reciprocating or vibrating principle. Let fig. 2 represent the section of a compound solenoid having a primary and secondary coil, the secondary being wound on the end. It is not difficult to make an iron model of a line of force, greatly magnified, no doubt; and for convenience of illustration some are hinged and suspended at the inner side near the equatorial part of the solenoid. Let the primary coil be excited, and these iron lines of force will repel each other, and strive to cut their way through the coil in order to assume the position shown by the dotted lines. In doing so they will have intersected the wire of the secondary coil, and have generated the inverse current. Break the primary circuit, and the magnetic lines cut the coil again, by falling back into their first position, generating the direct current.

When the magnetic lines remain in their extended position, by reason of the primary current, the rapid rotation of an irregular mass of iron near the end of the magnet would cause the lines of force to vibrate through the secondary coil and generate alternate currents similarly to an induction coil.

E. L. Voice.

October 6th, 1890.

#### The Elmore Copper Companies.

Assuming the Elmore process to be a success there is as much justification for a company to work it in every country which uses the metal as there is for an English company, and the probability is that one would be formed for Timbuctoo if occasion warranted. But the laws of political economy cannot, unlike, therefore, the copper industry, be revolutionised, and supply will always be subservient to demand, and Timbuctoo will be without its Elmore company.

It having been proved that the process is a success and valuable, no criticism will be logical which condemns the Austrian and French Companies without condemning at the same time every other Elmore company. To prove the value of the process two things have to be shown; firstly, that the tubes which are admitted to be produced, have intrinsic merit and consequently marketable value, and, secondly, that the cost of manufacture is commensurate with the price the product will obtain on the market. This is the nut-shell of the whole case, and whatever the results may be the connection of Messrs. Woodhouse and Rawson with the process neither makes it better nor worse.

An enquiry on the above two points would have elicited such information as I will give you, and with these facts before you, instead of condemning without

enquiry an invention you should encourage, your six columns might have been devoted to better purpose. Now, as regards the first point; every expert who has tested the tubes has satisfied himself that they are much stronger than those made in the ordinary way, and, as a matter of fact, the company guarantees that every tube it supplies shall have a tensile strength far above that of any tube of similar dimensions.

As to the second point, namely, the cost of production, the company is now, and has been for some time, working at an actual cost of  $\frac{1}{2}$  d. per lb. of deposit, and this statement has been confirmed by Dr. Hopkinson, who visited the works last week. This is, by the by, very much less than Mr. Elmore's original estimate, which, I think, came to over 1d. per lb. Now, I have shown on evidence which cannot be fairly disputed, that the company produces a superior article at a ridiculously low price; and the sole remaining point remains, Is there a market for the company's commodities? Given a better article at a lower price, common sense will tell one what the result will be.

The statement of Mr. Clark to which you refer in your article, has no bearing on the case, for the simple reason that he was alluding to ordinary electro-deposited copper, which for utility cannot be compared with Elmore copper; while as to the extract from Mr. Parker's report, with its obvious error in the proportion of the decrease of tenacity, no stronger evidence can be given of this gentleman's opinion than the fact that he has become a shareholder in the company since the date of his report.

Good wine, notwithstanding the old maxim to the contrary, does need "bush," and before anything can be appreciated at its true value, time, labour, and advertisement must ensue. I thoroughly believe in the impending revolution in the copper industry, but I am, although a shareholder in the Elmore companies and therefore, according to you, a fool, not sufficiently foolish to think that it will be effected in a few months.

A Shareholder.

#### The Sweating System.

Kindly allow me through the medium of your widely read journal, to call attention to the rapid strides that are being made in the electric lighting industry by that common enemy the sweater. Although our business is comparatively new, the sweater is there in all his glory, competing seriously with first class firms who pay fair wages which will cause them eventually to reduce theirs. It behoves both employers and employees, whose interests are inseparable, to make a determined stand against these men, and they cannot start too soon. Other trades, just lately, have had to fight this question out and undoubtedly we shall have to do so in the near future. It is not alone the small wages paid by these men, but it is the bad material that is put in, thus injuring our trade by the constant breakdowns that occur, and preventing intending users from adopting the light. The only remedy that I can see is by the first class firms combining and crushing the men off the market.

Being a member of the Electrical Trades Union, and knowing a great many, both union and non-union men, there is amongst them a genuine desire on their part to do something to eradicate this pernicious system, or we shall be obliged to work for little better than a starvation wage; and I am heartily ashamed to know that many of these sweaters originate from men of our own class. I should like to ask my fellow workmen what they are going to do? If they stand aloof they are against themselves and the men who desire to put a speedy end to this pernicious system. Hoping that the outcome of this letter will be to bring forward some practical suggestions from employers and employees,

An Electrical Trades Unionist.

## THE ELECTRO-DEPOSITION OF COPPER.

ACCORDING to determinations by Lord Rayleigh and Prof. Roscoe, a current of 1 ampère will in one second throw down from a solution of sulphate of copper .0050478 grains of the pure metal. To deposit, say, 20 tons in one week of 60 working hours, would require a current of

$$\frac{20 \times 7000 \times 2240}{.0050478 \times 60 \times 60 \times 60} = 287,620 \text{ ampères.}$$

Now, according to Sprague, the maximum allowable current for obtaining proper deposition is 18 ampères per square foot of surface of the electrodes; this, with the current above calculated, is equal to

$$\frac{287,620}{18} = 15,979 \text{ sq. ft.} = 127 \text{ ft.} \times 127 \text{ ft.}$$

Probably by the use of the burnisher, as in the Elmore process, a more granular form of deposit could be allowed, and a somewhat heavier current be employed per square foot of surface; but, in any case, the latter must be very large indeed. In order that the current named may be possible, the resistance of the circuit under an electromotive force of 1 volt must not exceed—

$$\frac{1}{287,620} = .0000034768 \text{ ohm,}$$

and this could not be obtained in a single depositing cell with the plates at a greater distance apart than a few inches only. Placing a number of depositing tanks in series would not make matters any better, for what is gained in one respect is lost in another. It would appear then that to deposit 20 tons per week would involve the use of enormous tanks, worked under conditions which would be practically impossible except at a heavy outlay for plant and tank space.

As regards the cost of deposition, to throw down 1 ton of copper under an electromotive force of 1 volt would require

$$\frac{2240 \times 7000}{.0050478 \times 746 \times 60 \times 60} = 1156.7 \text{ H.P. hours,}$$

taking the case of one depositing tank only being used.

Now the average cost in cities of 1 H.P. for one year, taking a working day of ten hours and six working days per week, is known to be about £10, which is equivalent to .76923d. per hour; to deposit, therefore, 1 ton of copper under a total electromotive force of 1 volt in one depositing tank would cost

$$\frac{1156.7 \times .76923}{12 \times 20} = £3.7072.$$

If the working electromotive force were less than 1 volt, then the cost would be proportionally less, but this, on the other hand, would involve a great increase in the size of the depositing tanks to enable the required current to pass. Of course the cost per ton would in actual practice be considerably more than the bare theoretical, as calculated above, as wages, factory expenses, depreciation on plant, interest on capital involved, and the many contingencies which will readily occur to everybody, have to be added, and these must be heavy, considering the extremely slow rate at which deposition takes place.

Now to show what occurs in actual working. In a well-known volume on electro-deposition we find the following:—"At the North German Works there are 40 baths arranged in two series of 20; the anode surface in each bath is nearly 325 square feet, giving a total of 13,000 square feet of surface for the whole of the baths. The copper is deposited on the cathodes to the thickness of about  $\frac{1}{5}$ th inch, and at the rate of about 64 lbs. per hour in all the baths, or 1,760 lbs. per day of 24 hours. The production is 1 lb. of pure copper with a consumption of 0.4 H.P. per hour." It will be seen therefore from this example of operating on a scale of nearly a ton per day that the production necessitates 900 H.P. hours per ton.

At the Elliott Metal Refining Company's Works, near Birmingham, there are employed vats arranged in five series of forty-eight in each. Each vat contains 16 anodes, weighing 26 lbs. each, which are replaced every five weeks, and the operation progresses for 156 con-

secutive hours per week, the yield of copper for the forty-eight baths being approximately 30 lbs. per hour, or about '65 lbs. per bath per hour.

Taking, then, into consideration the cost of solution, the replacement of anodes, and using a boiler and steam engine as the source of motive power, it is difficult to reconcile the report made by Dr. Hopkinson, who, whatever he may do in theory, will not get his horse-power hour for less than three farthings in practice, with what must be the actual state of affairs, and it is only right and just that the Elmore directors should lay before their shareholders and the public a detailed statement of the actual cost incurred in producing their wares.

It is possible that Mr. Stepney Rawson could help us to this desirable end, or if the authorities which we have mentioned have been erroneously quoted perhaps he will show where the flaw exists, as we hope to return to this subject more fully in another issue.

### THE JOHNSON STORAGE BATTERY.

A FORTNIGHT ago we received a letter from Messrs. Ramsden & Co., announcing the shipment from Boston, U.S.A., of a set of secondary batteries, manufactured by the Johnson Electric Supply Company. This letter stated, among other things, that "the battery is entirely novel in its construction, as also the method of combination of the active material and the lead plates, the active element being suspended in a net-work or box of lead—very rigid and firm in construction—while ample allowance is made for the necessary amount of expansion and contraction without the slightest warping or buckling in the plates." Reference was made to various tests undertaken by sundry experts, among which is one experiment "with 30 Johnson cells weighing about 21 lbs. each, running 14 16-candle power lamps from a single charging for 21 hours and 30 minutes, the rate of discharge dropping during this time from between 10 and 11 ampères to about  $9\frac{3}{4}$ ." The importers of this battery add the following statements:—"We think we have the storage battery of the future, as its capacity, efficiency, and durability, as well as cheapness of construction, are absolutely unprecedented. It is quite indestructible in any legitimate use required of a battery, actual short-circuiting and welding of iron wires upon a single cell having no deleterious effect upon the plates. Ten cells were charged in Boston before shipment, and will be drawn off at the electrical works in Westminster some day next week."

We were naturally anxious to see this remarkable invention, and test the accuracy of the above assertions, so when the invitation to view the cells arrived, we proceeded to the place of exhibition. Mr. Johnson, the inventor, kindly answered numerous questions put by several gentlemen present, showing the method of constructing the plates, and giving the following data upon the cells on exhibition. The set of eleven cells before us had been discharged at the works at Boston, and gave a capacity of 260 ampère

hours, working at the rate of 13·5 ampères; the E.M.F. at the commencement was 22 volts, and at the end of the discharge 18·91 volts. The weight of the electrodes in each cell was stated to be 33 lbs.; the total weight of each complete element, however, could not be ascertained. This performance shows no advance whatever upon well-known English types of storage batteries, and the arguments naturally turned upon questions of durability and cost. As to durability, the oldest cells have only been in use for two years, and we were not favoured with a view of samples of that age. As regards cost, we could not see how and why the plates on exhibition should be cheaper than those already in the market.

Mr. Johnson's plates are made of lead and oxides of lead, requiring as much material as any other lead battery. The plates consist of ribbed sheets of lead, perforated in such a manner that a "burr" is left on the inner side of each hole. Two such sheets are placed back to back, and the space between them is packed with a paste of red lead. We have been unable to discover any striking novelty in this construction, and we cannot see why such a lead plate should be "indestructible," no means being taken to prevent the sheet metal becoming oxidised with the rest. Mr. Johnson modestly acknowledged that to bring storage batteries to England was like taking coals to Newcastle, the industry here being more highly developed than in America, and he only yielded to the pressing invitation on the part of his London representatives, who issued the letter above referred to, and who are evidently under the impression that this is "the battery of the future." No doubt the "future" will decide whether this is so.

The Vaughan-Sherrin  
Battery.

WE are pleased to note that M. E. Hospitalier has not left us to do battle alone with Prof. Silvanus Thompson. From the last issue of *L'Electricien* we extract the following, which deals mainly with Dr. Thompson's tests:—"Notwithstanding the confidence we feel in our eminent colleague, it is impossible for us to accept his figures without making one important observation. Dr. Silvanus Thompson estimates at 9d. or 10d. (90 centimes to 1 franc) the price of the Board of Trade unit. But we see, according to the figures published, that there is consumed about 1 kilogramme of zinc, the price of which would not be less than 65 centimes ( $6\frac{1}{2}$ d.). It follows from this that the *special liquid* in which there must be sufficient active matter to dissolve this zinc costs only 35 centimes ( $3\frac{1}{2}$ d.). This seems very improbable, not to say impossible. We always receive with a certain amount of distrust these marvellous batteries that are said to supply electrical energy cheaper than the central distributing stations, and M. Vaughan-Sherrin's special liquid will not make us change our opinion, notwithstanding Prof. Silvanus Thompson's figures, and we are reminded of our great fabulist: '*Ce liquide spécial ne nous dit rien qui vaille,*' and also of the poet: '*Hélas! que j'en ai vu mourir, de jeunes piles.*' We hope our readers will pardon the liberty we have taken with the text, in consideration of our willingness to apologise when the miraculous—we beg pardon, the special liquid—becomes known to us."

Telephone Working.  
AT a recent paper read before the National Exchange Association, Detroit, America, a rather lengthy description was given by Mr. Carty of the "Bridging Bells" system of working telephone lines. The speaker seemed to be quite unaware that the method described had been for many years in use on the telephone systems worked by the Post Office in this country, and all details in connection with the same carefully worked out. A description of it is given in "The Telephone," by Preece and Maier.

The Electropathic Quack Again.  
MR. HARNESS, with his electropathic appliances, is once more to the front. This time it is that staunch conservative evening paper, the *St. James's Gazette*, that he has succeeded in beguiling. We had always imagined that the etiquette of respectable journalism had drawn a broad distinction between the space allotted for subject matter and advertisements, so that the public in reading should not be unwittingly drawn into perusing matter which they believe to be general news but which they find to be "puff," pure and simple. The *St. James's Gazette*, however, appears to have recognised no such difference, but in a recent number has allowed the prominent position which the journal has justly won as a temperate leading evening paper, to be made the means of furthering the ends of Mr. C. B. Harness. Thus, in the No. for October 6th, on the last sheet we find a whole column of matter printed in article type and arranged and headed in article form, solely devoted to the puffing of Mr. Harness's so-called electrical appliances. The editors of daily papers cannot be expected, of course, to be skilled electricians, and mistakes of an exceedingly absurd character with reference to the science are sometimes inevitable, but considering the wide-spread and known existence of quackery, especially of the electrical description, it is hardly too much to expect that reasonable care should be taken to protect the unsuspecting public from confounding advertisement with news items.

Copper.  
IN the lectures recently concluded at the Mining Exhibition, some interesting statements were made on the subject of copper. The lecturer on "Mining and Minerals in South Australia," spoke of the first discovery in that country made in 1842, viz., the Kapunda Copper Mine, which produced thousands of tons of ore, at the same time greatly benefitting the colony and bringing it into favourable notice as an important mineral country. Other discoveries quickly followed, and the Burra Burra Mine, which once supported an immense population, marked a new era in the history in copper mining in South Australia. The total amount paid in dividends in this concern was £800,000. After being worked by the original owners for some years, the mine was sold to a new company; but during the past two or three years the mines had not been worked, owing in some degree to the low price of copper, and also to the fact that the deposit then being worked apparently became exhausted. For many years the average yield was from 10,000 to 13,000 tons of ore, averaging 22 to 23 per cent. of copper. Other mines were opened, though the output was less, and many of these were now closed, but it was said that they would be shortly reopened, a fact which the lecturer urged would still further decrease the price of copper. Referring to the great "boom" in copper in 1861, which

caused the output to be tremendous, he said that at that period there were working in one mine alone 1,600 men. Copper mining has so far affected the wealth of the country in as much as two mines, opened about 1870, had down to the present time proved of value to the colony to the extent of seven million pounds. The fourth lecture, delivered by Mr. J. C. Gordon Sprigg, dealt with the mining industry in South Africa, in which copper had always played a strong part. Here was situate the Namaqualand copper fields, from which 400,000 tons had been sent to England.

Lamp Candle-powers.  
WE publish in our Correspondence Columns a very interesting letter on this subject, to which is attached a valuable table of tests, the like of which, we think, has not hitherto been published. These experiments were carried out by Mr. W. W. Melhuish, the chief-engineer of the station, and we have examined the lamp curves from which the figures have been taken. The superiority of the first-mentioned lamp will not fail to attract attention, but possibly some of the others have been much improved during the two years which has elapsed since the data was obtained.

Cable Laying and Maintenance.  
ONE of the clauses in contracts between submarine cable companies and manufacturers constitutes a grievance which, we expect, both parties would gladly see abolished. We refer to the final operation connected with cable submerging, the conditions of which are generally set out as follows:—"The cable shall be maintained and tested for thirty (consecutive) days after the completion of the laying at the sole risk of the contractors." If the cable is likely to go wrong through any inherent defect in its construction, it would show faulty in less time than thirty days. This clause has become customary because nobody has apparently hitherto attempted to show that it is unnecessary; it is a costly business for both manufacturers and owners of cables, and the sooner the maintenance clause is limited to a week, or even less, so much the better for everybody concerned. The public would not only be enabled to send messages at an earlier date, but the cable companies would naturally save vast sums of money which of course the contractors allow for in their estimates, and their shareholders would thus derive extra benefit. Possibly the thirty days' guarantee might have been advantageous in times gone by when cable manufacture and testing were not thoroughly understood, but to-day it is but the perpetuation of an old, and now more or less useless custom, and should, therefore, be either abandoned altogether or so modified as to meet the requirements of modern practice.

Distance of Telephone Working.  
IN the article on "Telephonic Specific Inductive Capacity," by Mr. W. W. Jacques, which we publish in our present issue, it is stated that the good speaking limit, or "K R," over a telephone line with a Blake transmitter is 2,000 and with a Hunnings transmitter 4,500. These figures differ materially from those obtained, as the result of numerous experiments, both on aerial lines, underground wires, and artificial cables (combinations of condensers and resistance coils) in this country. The average good speaking limit on overhead copper wires is found to be 10,000, on cables and underground wires 8,000, and on overhead iron wires 5,000, but then a Gower-Bell instrument was used.

## ELECTRICAL OSCILLATIONS IN AIR.\*

By JOHN TROWBRIDGE and W. C. SABINE.

THE experiments of Hertz on electrical waves have opened a wide field for investigation in electromagnetism. The qualitative results of Henry and of Feddersen have been expressed in a quantitative manner by Sir William Thomson. Hertz, collecting together the results of previous observers, and reasoning upon the factors in the formula of Sir W. Thomson, which expresses a relation between the capacity of a Leyden jar and the self-induction of the circuit through which this jar is discharged, has detected wave-motion with its nodal points and ventral segments, on a wire over which electrical oscillations take place.

Hertz has also pointed out that the experimental results confirm Maxwell's theory, that light and heat are electromagnetic phenomena, and that all energy comes to us from the sun in electrical pulsations.

There can be no question of the phenomena of so-called resonance discovered by Hertz. Roughly speaking, the results obtained by Hertz resonators

satisfy the formula  $t = \frac{2\pi}{v} \sqrt{LC}$  in which  $t$  is the

period of the electrical oscillations,  $L$  is the inductance of the circuit, and  $C$  is the capacity of the jar, or that of the terminals between which the electrical discharge takes place.

Prof. J. J. Thomson has based a method of measuring the capacities of dielectrics upon this formula and upon Hertz's work †.

The researches of Feddersen upon electrical oscillations ‡ were more quantitative than those of Joseph Henry § and Lorenz §, by his repetition of Feddersen's results, and by his mathematical analysis of them, apparently gave subsequent observers a solid basis for calculation.

The results of Feddersen and of Lorenz were obtained by photography. An image of the electric spark drawn out by means of a revolving mirror was photographed, and the distances between the successive oscillations, shown by dark bands on the photograph, were measured. Lorenz assumed the ratio between the electrostatic units and the electromagnetic units,  $v = 300 \times 10^6$  metre, as that of the velocity of light; and by means of

the formula  $t = \frac{2\pi}{v} \sqrt{LC}$  obtained a satisfactory

agreement between the result of experiment and the theory. He showed, apparently, that a certain lack of agreement between theory and experiment, which Feddersen had noticed, was due to taking the dielectric constant of glass too small.

It will be noticed that the method of Feddersen, by means of which the electrical oscillations are photographed, apparently affords an accurate method of determining  $v$ . For the factors  $L$  and  $C$  occur under the square root, and the percentage errors of determination of  $L$  and  $C$ , being under the square, are halved. Lorenz did not repeat the entire work of Feddersen, but only obtained a sufficient number of photographs—taken under definite conditions in regard to capacity and inductance of the circuit—in order to measure  $t$ , the time of oscillation. The accuracy of the results which can be obtained for  $v$  depends upon the limits of accuracy of the measurements of the photographs, and of the determinations of the dielectric capacity for oscillatory charges.

In reasoning upon the mode of electrical oscillations in dielectrics, it occurred to us that the medium of the dielectric must greatly influence the result. At the instant the electrical oscillations occur, the glass of the

Leyden jar is subjected to a strain which is more or less periodic. It is not probable that the capacity of a condenser is the same for rapid charges and discharges as for slow ones, and the measurements of capacity by the ordinary slow methods form no criterion of the capacity of glass under electrical influences which last but three millionths of a second. We therefore concluded to employ an air condenser instead of one of glass, in order to detect, if possible, the effect of the medium of the dielectric upon electrical oscillations. In order to obtain sufficient capacity for a suitable spark, we were obliged to use the cylindrical form of condenser. The first condenser we employed was made of sheet zinc and consisted of 19 coaxial cylinders. The inner cylinder had a diameter of 15.1 centim., and the outer one of 60.4; the height of the cylinders was 92 centim.

The capacity was computed from the formula

$$C = \frac{1}{2} \frac{l}{\log \frac{b}{a}};$$

in which  $l$  is the height, and  $b$  and  $a$  are radii.

A correction for the ends was made as follows:—The radius of curvature of the boundary of the cylindrical plates was considered so large in comparison with the distance between them that the boundary was treated approximately as a straight line. We may consider that each zinc cylinder constituted a plate between infinite imaginary planes which were at zero potential, these planes being equipotential surfaces. The zinc cylinder was supposed to have its area extended by a strip of uniform breadth around its boundary, and the surface density was assumed to be the same on the extended plate as on the parts not near the boundary. Following Maxwell (Vol. I. Section 196), we have

$$\frac{B}{\pi} \log_e 2 \cos \frac{\pi \beta}{B} \text{ for the correction for length.}$$

$B = a - b =$  distance between cylinders.

$\beta =$  thickness of cylinder.

$l =$  height of cylinder.

This air condenser was connected with a circuit of parallel wires, which was carefully strung by means of silk thread through the centre of a large unoccupied room. The length of this circuit was about 50 feet. It returned upon itself to the sparking terminal of the air condenser. The jar was charged by a Holtz machine, which worked fairly well under all conditions of the atmosphere. The revolving mirror was a plane one,  $4 \times 5$  inches, silvered upon the front face. It revolved upon a horizontal axis with an average speed of 3,000 revolutions per minute. The frame which carried the mirror bore also a brass arm provided with a minute brush, which rubbed upon a brass sector let into a large disc of ebonite. When the brush rested upon this brass disc the electrical charge could pass to two terminals of tin, between which the discharge took place. A concave silvered glass mirror, of 313 centim. radius and 16.5 centim. aperture, placed at a distance of 230 centim. from the spark, received the image of the spark and reflected it back to the revolving mirror. From the revolving mirror the image was reflected to a photographic plate, which was at a distance of 259.7 centim. from the rotating mirror.

The adoption of a plane revolving mirror, and a stationary concave mirror of long focus, enabled us to place the photographic plate at a distance from the revolving apparatus, and therefore to employ less speed for the revolving mirror. There was no sensible aberration of the image. Great care was taken to balance the mirror. Its large size and weight made it very important, on account of the danger of the apparatus flying apart, that it should revolve with uniformity. The axis of the mirror was placed horizontally. This precaution proved to be a wise one, for twice during the course of the many runs which were made the mirror flew into pieces; the excursions of the fragments, however, were confined to a vertical plane. This liability to accident is perhaps inherent in a method which employs a large plane mirror. The increased

§ Wiedemann's *Annalen*, vol. vii., p. 161 (1879).

amount of light which results from the use of a large mirror, however, forms a valuable compensation. The revolving mirror was driven by a gas engine.

In order to determine the speed of the mirror at the instant the spark passed, the following apparatus was devised. The same shaft which carried the revolving mirror also carried a brass cylinder 5 centim. in diameter and 21 centim. long. This cylinder was covered at each trial with paper which was coated with lampblack. A stylus moving along a stationary rod beside the shaft could be made to draw a spiral upon the revolving cylinder. One terminal of a Ruhmkorff coil was connected with the brass cylinder, and the other with the stylus. A second pendulum was made to break the circuit of the primary of the Ruhmkorff coil at intervals of one second, and at the middle point of its swing. When the stylus was drawn along the stationary rod which served to guide it, it was made to release automatically at the beginning of the second another pendulum held up by an electro-magnet. This latter pendulum, at the middle of its swing, discharged the air condenser through the inductance circuit at the instant that the mirror was in a suitable position to reflect the image of the electric spark into the photographic camera. While the stylus was being drawn upon the revolving cylinder, the spark from the Ruhmkorff coil left its trace upon the blackened paper. The record on the chronograph consisted of a strongly marked spiral line of over fifty turns. The two sparks from the Ruhmkorff coil left their trace upon the blackened paper as spires, which therefore measured the number of revolutions of the cylinder between the swings of the pendulum, and thus gave the rate at which the mirror was revolving. The chronograph record enabled us to measure the time to  $\frac{1}{3000}$ th of a second.

In any operation which requires that an electrical spark should make a record upon a disc or cylinder revolving at great speed, a large Ruhmkorff coil and a strong battery are necessary, especially if the primary circuit of the Ruhmkorff coil is broken by a pendulum. With the ordinary automatic break, such as is commonly employed upon induction coils, the failure of a single break is unimportant. If, however, a single break fails when a pendulum break is employed, the record of the experiment is an imperfect one. An excess of battery power and a large battery are therefore necessary. A metallic breakpiece also was found to be more inconstant for our purposes than a mercury break.

It was found that a certain simplicity of contrivance was necessary in the method of discharging the air condenser through the inductance circuit. No arm connected with the revolving mirror could be trusted to break or make an electrical circuit by throwing in or out any form of switch. The great speed at which it revolved broke all arrangements which were tried. By placing a short stiff brush of minute size upon the end of the flying terminal connected with the revolving mirror, and allowing this brush to rub against a brass plate set in an ebonite circle of 41 centim. in diameter, constancy of action was secured.

In order to obtain the same difference of potential at each run, experiments were first made with various forms of unit jars and pith-ball electrometers. These devices were speedily given up in favour of a simple balance electrometer. One of the pans of a delicate balance was replaced by a metallic disc. A similar disc, which was stationary, was placed immediately below the movable one. By properly weighting the remaining balance pan great delicacy and range of indication were obtained. This apparatus constitutes, in fact, an absolute electrometer. A suitable guard ring can be placed around the movable disc.

When the air condenser had been charged to a definite potential, the movable disc of the electrometer closed an electrical circuit in which was included an electrical bell. The observer stationed at the chronograph, at the instant he heard the bell, drew the carriage connected with the stylus along the guides which kept the stylus on the blackened cylinder.

Calling  $L$  the coefficient of self induction, we have

$$\frac{L}{l} = 2 \log \frac{b^2}{a^2} + 1^*$$

in which  $l$  is the length of conductors contained between two parallel planes;  $b$  the distance apart of the conductors;  $a$  the radius of wires.

In our case the effect of the ends was found to be inappreciable. The induction due to the ends can be calculated by the repeated employment of the formulæ for geometric mean distance† for two lines whose directions intersect at right angles.

Lord Rayleigh has given the following formula for inductance under rapid oscillations:—

$$L' = l \left( A + \sqrt{\frac{\mu R}{2 \rho l}} \right);$$

in which  $A$  is a constant, depending on form of circuit;

$\mu$  is permeability;  $R$  is resistance;  $\rho = \frac{2\pi}{t}$ , where  $t$  is time of oscillation;  $l$  is length to and fro of inductance circuit.

The final value of  $L'$  for our case is  $L' = 39,697$ .

The radius of the wire employed was  $a = .0501$  cm.

The length was measured in three sections:—

No. 1, length	1197.0	cm., distance between wires	$b_1 = 31.55$ cm.
No. 2, „	281.0	„ „	„ $b_2 = 16.1$ cm.
No. 3, „	103.0	„ „	„ $b_3 = 11.3$ cm.

The ohmic resistance of the wires was  $.742 \times 10^9$  for direct current, and  $1.54 \times 10^9$  for alternating currents of period  $t = .0000031$ .

The difficulty in the process of photographing the spark consisted in discharging the air condenser through the induction circuit at the instant the revolving mirror was in a position to reflect the image of the spark to the photographic plate. The terminal connected with the revolving mirror, which allowed the electrical discharge to pass when the mirror was in the desired position, had to be adjusted with extreme care. The speed of the image at the photographic plate was about 1 mile per second.

The photographs were measured by means of a dividing engine. At first an objective of low power was used on the microscope of the dividing engine. It was found, however, that a simple cross hair, unaided by a lens, moving directly against the negative, was better than any eyepiece. Measurements were made of the intervals between the electrical oscillations at both terminals.

In later experiments a smaller air condenser was employed, for reasons which will appear in the conclusions of our paper.

A summary of the details and dimensions employed is given herewith.

Small air condenser (No. 2), cylindrical.

19 zinc cylinders.

Height 30.47 centim.

Diameter of inner cylinder 7.60 centim.

Diameter of outer cylinder 25.95 centim.

Average distance apart .5 centim.

Capacity (geometric) 5317.9 absolute units—corrected for the capacity of ends.

Capacity of wire, 200.

Self-induction in three sections, radius .0501.

1. Length, 1197.

Distance apart of parallel wires, 31.55.

2. Length, 281.

Distance apart, 16.10.

3. Length, 103.

Distance apart, 11.3

For alternations of slow period.

Ohmic resistance, .742.

Self-induction, 41,090.

Theoretical time with these values, .00000310 sec.

For alterations of period, .00000310 sec.

Ohmic resistance, 1.54.

Self-induction, 39,700.

Theoretical time, .00000304.

	{ Left	3·30	3·43	3·42	3·43	3·42	3·50	

Fig. 7 shows that the length of the spark exerts an inappreciable effect,

The values for the different negatives are plotted in fig. 1, 2 ; the mean values, in figs. 3, 4. The time of the first half-oscillation was doubled in plotting. On each ordinate is plotted the time of one oscillation—on the first ordinate the time of the first oscillation, on the second the time of the second. It should be noted that the curved lines are meaningless, except where they cross the vertical ordinates, serving merely to connect the points belonging to one negative.  
The difference in the time of oscillations cannot be

explained by the vibration of the discharging arm lengthening and shortening the sparking distance, since this would necessitate a vibration frequency of 100,000 per second, and an amplitude of at least one millimetre; a velocity and momentum impossible for the apparatus either to acquire or endure. This cause also would tend to make the variation range equally above and below the calculated value as the sparking distance increased or diminished.

Another explanation may be sought in the varying ohmic resistance of the path of the spark, although this explanation is inadequate to explain the whole effect. In order to test it, a long (1.3 centim.) and short (.4 centim.) spark were taken from a glass Leyden jar (see fig. 7). Not only could no appreciable difference between the two plates be detected, but there was no variation in the time of successive oscillations.

In regard to the measurement of the negatives on the dividing engine, the following points may be worthy of mention. At the time the measurements were made, it was expected that the sparks from the glass condenser would show the variations, and that the air condenser would give the constant and theoretical period of oscillation. The reverse of this appeared when the results of the measurements were reduced. Moreover, the measurements were made by a run of the dividing engine from one end of the negative to the other; so that if an error was made in the setting of the cross hair on the image of one discharge—for example, making the measurement of that oscillation large—a corresponding amount would be deducted from the measurement of the next oscillation. The result of this would be that if the apparent variations were due to errors in measurement, the periods of discharge would be alternately large and small, or at least as often and as far below the theoretical value as above it. But this is conspicuously not the case.

A consideration of the curves which represent our results shows that with quick oscillations which result from the employment of a small air condenser, the air dielectric did not have time to recover completely, in the time of one oscillation, from the strain to which it was subjected. With the larger air condenser, the oscillations being slower, more time was given for this recovery, and hence the periodicity which we have discovered was not so marked. It seems, therefore, that not only should an electrical resonator be turned for capacity and self-induction, but also for a certain periodicity of strain in the dielectric.

In the case of glass, we should not expect to obtain evidence of this periodical recovery from a quick strain, since it is well known that the recovery from strain is so slow that the discharge from a Leyden jar is incomplete after a discharge lasting a second. The curve we give for glass (fig. 7) shows that this periodical recovery is too slow to manifest itself during the time of quick oscillation.

It is perhaps unnecessary to call attention to the fact that the capacity of a dielectric for rapid discharges is very different from its capacity for slow discharges. In the paper of Lorenz, already cited, the value of the dielectric capacity of glass was determined by slow methods, and used to test an equation in which the capacity of glass appears under very rapid charging and discharging.

Boltzman\* and Klemencint† have experimented on the specific inductive capacity of gases and vapours, and it is seen from their results that the agreement between the square root of the capacities of the simple gases and  $\mu$ , the index of refraction for light of these gases, is quite close, as is demanded by Maxwell's electromagnetic theory of light. A marked difference, however, was found to exist in the case of more complicated molecules—sulphurous acid, or ethyl bromide, for instance. It is probable that the changes of specific capacity of heterogeneous media under rapidly alternating forces constitute an important factor in consider-

ing the possible agreement between Maxwell's theory of light and the results of experiment.

In order to see if an intense magnetic field could modify the transmission of electrical waves through a dielectric, the following experiment was tried. A glass Leyden jar, 2.5 centim. in diameter and 28 centim. in height, connected with our inductance circuit, was placed inside a coil consisting of 728 windings of large wire. The outer and inner radii of this coil were 27.7 centim. and 34 centim. Its height was 40.5 centim. The magnetic field in this coil was supplied by a Gramme machine, which gave a current through the coil of approximately 30 amperes. It was expected that a certain amount of the energy spent in producing the electrical waves would be consumed in a reaction on the magnetic field. The total duration of the electrical discharge did not appear to be notably affected by the magnetic field. Certain experiments seemed to show a decrease in the total number of electrical oscillations. A large number of experiments will be necessary to decide upon the effect of a magnetic field upon the passage of electrical waves through a dielectric. The difficulty of obtaining an electrical discharge under the same difference of potential made the experiment an extremely difficult one. The method seems to us to promise a discovery of Maxwell's displacement currents in dielectrics; and we are therefore continuing our researches in this direction with a modified form of apparatus.

#### Conclusion.

1. The electrical oscillations in the air between the plates of an air condenser show a periodicity extending through the entire range of oscillations. We believe that this periodicity is the analogue of the phenomenon of hysteresis in magnetism. A certain amount of the energy of the electrical discharge is spent in overcoming the dielectric viscosity of the air and in straining the air dielectric. This strain is not immediately released in unison with the electrical surging.

2. The discussion of our entire results shows unmistakably that electrical oscillations in air are not represented fully by the theoretical equations employed by Hertz. Since the latter writer has taken the term *resonance* from the subject of acoustics, and has given it a new significance in relation to electrical waves, we are tempted to draw also an analogy from the subject of sound. Laplace showed that the discrepancy between the value for the velocity of sound in air calculated from the theoretical equation, and that obtained by experiment, was due to a transformation of energy in heating and cooling the air during the passage of the sound wave. Our experiments on the transmission of electrical waves through the air show also that the values calculated from the theoretical equation do not agree with the experimental values. The discrepancy, we believe, can be explained also by a consideration of the transformation of energy in the dielectric.

3. The periodicity which we have studied is most manifest when the variable capacity of the air condenser bears a suitable relation to the time of the electrical surging.

4. The electrical waves are apparently unaffected by passing through glass which is placed in an intense magnetic field, the direction of the electrical strain being perpendicular to that of the magnetic strain. The displacement currents of Maxwell in this case do not appear to affect the time of electrical surging. This conclusion, however, may be modified by experiments which we shall try on a more extended scale.

---

**Telephone License.**—We are informed that the Secretary of the Post Office has intimated to Mr. A. Erskine Muirhead, Cart Forge, Glasgow, that he will grant him a license for telephonic communication. This, he claims, will enable him to make a public trial of the French telephones, which was refused him by the National Telephone Company.

† Abstract of Journal of the Society of Telegraph Engineers (1886), p. 108.

TELEPHONIC SPECIFIC INDUCTIVE  
CAPACITY.\*

By WILLIAM W. JACQUES,

Electrician of the American Bell Telephone Company.

IN a paper on "The Construction of Telephone Circuits," read before the American Academy of Arts and Sciences on the 15th of June, 1887, the writer of the present article pointed out "that the readiness with which telephonic conversation may be carried on over any circuit, whether made up of cables or pole lines, or both, depends:—

"1. On the total electrical resistance of the circuit joining together the two stations.

"2. On the total electrostatic capacity of this circuit."

And the general rule was laid down:—"No matter what may be the distance between two points, good business conversation may be carried on between them, provided they be connected by a pole line or cable, or both, the product of whose total resistance by its total capacity is less than 2,000, if transmitters of the Blake type be used, and less than 4,500 if transmitters of the Hunnings type be used."

This rule was enunciated as the result of an extended series of experiments carried out in England, France, Germany, and the United States on pole lines, cables, and mixed pole and cable lines, varying widely in mechanical and electrical dimensions.

The same law, only applied to the transmission of signals through submarine cables, had been previously worked out mathematically by Sir William Thomson, and amply confirmed by experience, so that to-day there can be no doubt of its truthfulness. It is evident, therefore, that in the construction of a telephone line, it is desirable to reduce both the *resistance* and the *capacity* to a minimum.

In a pole line, since the wire is suspended high above the earth, the capacity is always small, and the resistance is the factor that we must try to keep down. In cable lines, however, where the conductor is necessarily brought near to other conductors, or a metal shield, or the earth, the capacity becomes quite an important factor to be respected. In lines made up, as is most generally the case, of a comparatively short section of cable and a larger section of iron pole wire, the capacity of the cable becomes pre-eminently the factor to be respected; for, since the limit of conversation is here determined by the product of the capacity of the cable and the resistance of the whole line, a small percentage of saving in the capacity of the cable gives an enormous gain in the readiness with which conversation may be carried on over the line.

It becomes of vital importance, therefore, to choose an insulating material for telephone cables of low specific inductive capacity. Further than this, since it is well known (Gordon's "Electricity and Magnetism," Chap. XI.) that the specific inductive capacity of any insulating material, and consequently the capacity of any cable insulated with it, is very different for telephone currents from what it is for telegraph currents, because the charge and discharge take place so much more frequently, we may say that it is of vital importance to choose an insulating material of low "telephonic specific inductive capacity," using this expression in contradistinction to "telegraphic specific inductive capacity," by which we mean the values measured in the old-fashioned way.

In the *Proceedings* of the American Academy for December 11th, 1889, Messrs. Safford and Holman, two graduates of the Massachusetts Institute of Technology, in the Department of Electrical Engineering, have published the following table of telephonic specific inductive capacity of various insulators used in cable construction. This table is a result of an elaborate and careful research undertaken by them.

TABLE OF SPECIFIC INDUCTIVE CAPACITIES,  
MEASURED BY TELEPHONE CURRENTS.

1. Petroleum	...	...	...	...	1.6
2. Solid paraffin	...	...	...	...	2.0
3. Cotton saturated with paraffin in vacuum	...	...	...	...	2.0
4. Cotton boiled in paraffin	...	...	...	...	2.6
5. India-rubber	...	...	...	...	3.7
6. Artificial gutta-percha	...	...	...	...	3.9
7. Gutta-percha	...	...	...	...	4.2
8. Glass	...	...	...	...	4.6
9. Water	...	...	...	...	6.3

Realising that these results were of great practical importance in the construction of telephone cables, the writer has repeated the experiments of Messrs. Safford and Holman with entirely concordant results.

Let us see some of the conclusions we are obliged to draw from the data thus furnished, and then, in order to confirm these conclusions, we will describe some further experiments in this line.

I. The specific inductive capacity of any insulator used in the construction of telephone cables, and, consequently, the actual electrostatic capacity of any given telephone cable, ought to be measured with charges and discharges of telephonic frequency, and not by the old-fashioned method of measuring capacities by slow charge and discharge. This last is of no value, while the telephonic capacity is of vital importance.

II. The presence of water in an insulating material greatly increases its telephonic specific inductive capacity. An inspection of this table shows that, so far as capacity is concerned, petroleum is the best substance to be used, and doubtless this would be the case were it possible to keep it free from water, but water, we see from the table, has a specific inductive capacity of 6.3, so that its presence in the petroleum raises the capacity from the lowest to the highest in the list.

This observation is borne out by actual experience with cable No. 1 in telephony. When new, and the petroleum dry, it works excellently; but as water finds its way in, the cable rapidly loses its efficiency for telephonic work.

This action of the water is quite different from its action as a *conductor* to produce leakage, for the loss of electricity due to leakage in such a cable that has lost its efficiency from the presence of moisture, is entirely insufficient to account for the deterioration.

So, too, in the cable, No. 4, the presence of moisture exercises a detrimental effect on the power of the cable to transmit telephonic currents, and increases the inductive cross-talk to a degree that cannot be accounted for by the diminished insulation resistance.

It is proposed to show later that the presence of moisture in a lead covered cable, does actually increase very greatly its telephonic capacity, and, consequently, both the retardation and cross-talk.

III. Next to petroleum, solid paraffin is seen to be the best substance to use; but on account of mechanical difficulties it has never been found practicable to coat wires directly with solid paraffin.

If the wires are wound with cotton and then boiled in paraffin, as they are in making cable No. 4, the specific inductive capacity is raised to 2.6, an increase of 30 per cent., which, we have seen, is a very great detriment.

If, however, the wires are wound with cotton, and the air and moisture removed by the aid of heat and a vacuum, and they are then boiled in paraffin, from which the air and moisture have also been removed by heat and vacuum, the specific inductive capacity again falls to 2.0, which is the same as that of solid paraffin. This is the process used in preparing the cable No. 3.

It is probable that the inferiority of cable No. 4, as compared with No. 3, is due largely to the moisture retained in the cotton, which we have seen has a capacity of 6.3.

Leaving the paraffin cables, rubber is the next best, then gutta-percha, and poorest of all is glass; but all of these latter substances have so high a specific inductive capacity as to entirely unfit them for telephonic work.

It now becomes desirable to put this information in

\* New York Electrical Engineer.

more available form, for the use of those upon whom the selection of the best cables for use in telephone construction devolves.

Accordingly, I have given in the following table, first, the telegraphic capacity; second, the calculated telephonic capacity; and third, the measured telephonic capacity of one mile each of cables Nos. 3, 4, 5 and 7, all constructed on the dimensions of the "conference standard."

The measurements of the cables Nos. 3 and 4 were made on cables actually constructed in accordance with the requirements of the conference standard. Those of the rubber and gutta-percha cables were made on cables of a different specification, but reduced to the conference standard by well known and accurate methods of calculation.

*Capacity of One Mile of Conference Standard Cable,  
in Microfarads.*

	Measured tele- graphic capacity.	Calculated tele- phonic capacity.	Measured tele- phonic capacity.
Cable No. 3 .....	·18	·18	·18
" " 4 .....	·19	·24	·26
" " 5 .....	·27	·30	·30
" " 7 .....	·40	·40	·40

In order to show how great a difference in the practical working of a line this difference in telephonic capacity makes, let us assume a conversation to be carried on between two subscribers, connected by five miles of conference cable, and 40 miles of No. 12 iron pole wire.

Let us first suppose cable No. 3 of the conference specification be used.

Resistance 40 miles No. 12 iron wire = 1,184 ohms.

" 5 " cable ... = 175 "

Total line resistance ... = 1,359 "

Capacity 40 miles No. 12 iron  
wire (30-foot poles), = ·48 microfarad.

Capacity 5 miles Nos. 3 cable = ·90 "

Total line capacity ... = 1·38 "

Product of total resistance and capacity (1,359 × 1·38) = 1,875, which product, being considerably less than 2,000, shows us that conversation could easily be carried on over such a line with Blake transmitters.

Let us next suppose cable No. 4 of the conference specification to be used.

Resistance 40 miles No. 12 iron wire = 1,184 ohms.

" 5 " cable ... = 175 "

Total line resistance ... = 1,359 "

Capacity 40 miles No. 12 iron  
wire (30-foot poles), = ·48 microfarad.

Capacity 5 miles cable No. 4 = 1·30 "

Total line capacity ... = 1·78 "

Product of total resistance and total capacity (1,359 × 1·78) = 2,419, which product is considerably above 2,000, and good commercial conversation could not be carried on with Blake transmitters.

## THE TELEGRAPH DEPARTMENT OF QUEENSLAND.

THE Report of the Superintendent of Electric Telegraphs, Mr. A. F. Matveieff, concerning the telegraph branch for the year 1889, is briefly as follows:—

Since the last annual report, May 1st, 1889, the total mileage of extensions completed, dismantled lines, &c., deducted, amounts to 473 miles of line, 521 miles of wire. Several hundred miles are in course of construction. There are now 9,662½ miles of line, and 17,193 miles of wire open for public business.

At the close of 1889 there were 343 stations in daily

operation, and 721 officers employed, including those holding appointments in other departments, but exclusive of assistants at country stations (officers' wives), and construction parties. Since April 26th, 1889, 17 new stations have been opened, and one station closed, and 14 official stations added.

The twelve months which ended on March 31st last will long be remembered by the officers of the telegraph branch of the post and telegraph department as a period of unprecedented floods, damage to lines, delays to business, and difficulty and danger in many instances in restoring communication and effecting repairs. The total number of interruptions of all kinds in the southern and western districts was 1,007, caused principally by crosses with telephone wires, faults in railway offices, rotten trees falling and trees blown on lines, crosses caused by high winds, pins broken, insulators and brackets damaged; trees felled on lines by road parties, railway contractors, selectors, and others; damages by lightning (17 only). Also a few by large birds coming in contact with the wires; highly laden teams catching wires; hoop iron, fencing wire, tie wire, and fine wire hanging on main wires, in some instances occasioning serious interruptions before found (many of these, it is even feared, were purposely caused by evil intentioned people); blasting operations, land slips, &c., &c. An interruption was also caused by a large snake twisted in the wires, and another by flying foxes.

The expenditure on maintenance and repairs for 1889 was as follows:—Southern and Western districts, £5,473 7s.; Northern district, £3,769 13s. 11d.; total, £9,243 0s. 11d.

So far as interruptions to the cables are concerned, this has been the most unfortunate year experienced. On the 3rd of May, 1889, the cable at Flat-top Island was broken by a steamer's anchor, and hardly had the officer sent to repair it returned to Brisbane, when another misfortune of the kind occurred. Its position was then altered, and about a knot of new cable inserted. It worked well till January of this year, when it was again damaged by the heavy gale blowing at Mackay in that month; this necessitated another repairing job and the expenditure of 450 fathoms of new material. In May, last year, a bad interruption to the Thursday Island cable was caused by the A.U.S.N. Company's steamer *Victoria* drifting down, fouling, and tearing it from its moorings on the Thursday Island beach. The harbour authorities at once took steps to, if possible, recover the end, but were unsuccessful, this cable being of a very heavy type, and beyond the power of any appliances that might have been on the island to recover and re-lay. Very fortunately, the Eastern Extension Cable Company's steamer *Sherard Osborne* was on her way through Torres Straits to New Zealand at the time, and the General Inspector N.D. (Mr. Bourne), who had been sent from Bowen at the first intimation of the disaster, succeeded in making arrangements for the vessel named to pick up, repair, and re-lay the cable. A new piece of 350 fathoms had to be inserted, so much damage had been done.

Recently the cable between Woody and Fraser's Islands showed symptoms of leakage, which quickly increased. The electrician (Mr. Starke) went up as soon as possible, and, discovering the fault, found it advisable to insert about 55 fathoms of new. This, with the interruption of two small cables near Brisbane completes the list.

At the present moment all the submarine wires are working perfectly.

Since last report the new Telephone Central Exchange has been completed, the multiplex board fitted, and the wires removed from the old exchange. More of the Felton-Guilleaume cable has been brought into circuit, and is most satisfactory in its working. The various country exchanges are working well, and although in some places the number of subscribers has decreased there is every reason to expect, with a revival of business, an increased number of applications for connection with the exchanges.

THE ELECTRICAL RESISTANCE OF METALS.

By M. H. LE CHATELIER.

I HAVE shown, in a previous communication (*Comptes Rendus*), how the determination of electrical resistances can be turned to account for the study, at high temperatures, of the molecular transformations of metals. I propose to-day to extend the applications of this method to a new series of metals and alloys.

The metals that show no molecular transformation before fusion, possess electrical resistances, the variation of which is a linear function of the temperature. Here are some examples :

Resistance in ohms of wires 1 millimetre in diameter.

Pt	...	...	0.140	+	0.000325 t
Pt + 10 per cent. Rh.	...	...	0.335	+	0.000350 t
Cu	...	...	0.032	+	0.000101 t
Cu + 10 per cent. Sn.	...	...	0.150	+	0.000109 t
Cu + 20 per cent. Ni.	...	...	0.420	+	0.000110 t
Ag	...	...	0.023	+	0.000105 t

It will be observed that copper, silver and their alloys have an incremental coefficient that is to all intents identical, amounting to about 0.000105 ; that of platinum and its alloys is three times as great. Generally speaking, the introduction of small quantities of foreign substances into a metal raises its resistance curve, causing it to take a direction parallel to its original position. Silver showed an interesting peculiarity. On being heated in oxygen, its resistance curve remained perfectly rectilinear, its mechanical properties were not modified, and its melting point was found to be 945°, given by M. Violle. When, on the other hand, it was heated in hydrogen, all its properties were modified after 650° ; the electrical resistance increased more rapidly than in oxygen ; the metal, after cooling, was extremely fragile ; wires .25 of a millimetre in diameter could be bent without being broken. And, lastly, the melting point fell to 915°. The metal assumes a dull appearance similar to that occasioned in palladium by the decomposition of its hydruet (hydrure). These facts show that silver absorbs hydrogen at red heat. I found that the quantity of hydrogen absorbed is insufficient to form a definite combination and that, after cooling, the metal does not retain it in any appreciable quantity.

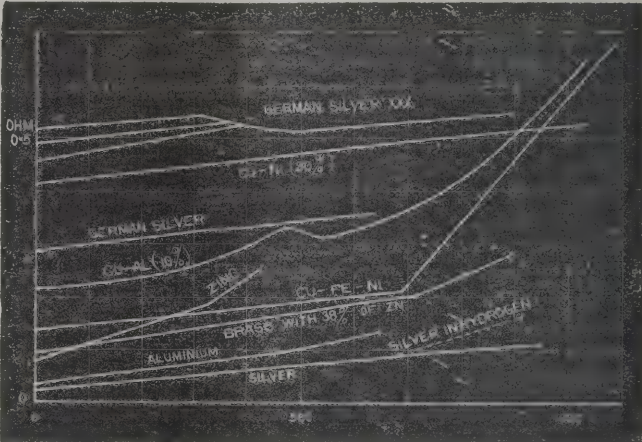

Many metals show, like iron, sudden molecular changes, produced at certain fixed temperatures. At these temperatures the electrical resistances undergo no change on passing one of these points of transformation as it does at the melting points. The accompanying curves give different examples of these phenomena. They were most clearly shown with an alloy consisting of Cu = 70, Ni = 18, Fe = 11. The temperatures at which molecular transformations occurred were found to be for the three following metals :

Zn.	Brass containing 38 per cent of Zn.	Alloy—Cu—Fe—Ni
360°	720°	690°

I ascertained directly in the case of brass that the transformation is accompanied by a considerable absorption of latent heat.

Some alloys show progressive molecular transformations, reminding one of those observed in the chemical equilibrium of saline solutions, in solutions of salts of chromium, of chloride of copper, &c. The transformation is not sudden, but is more often effected within certain limits of temperature. This is the case with slightly silicious aluminium bronze, the transformation of which takes place between 550° and 650°. It is

above this last temperature that the tempering of the metal is effected. But this peculiarity is shown in a marked degree in German silver and in alloys of copper and nickel. When these alloys are heated, their resistance decreases rapidly between 300° and 500°. In order to observe this phenomenon, it is indispensable that we should obtain metal that has been annealed (recuit) and cooled very slowly. In the case of German silver, we can only avoid its being almost completely tempered, by making the fall of temperature from 500° to 300° occupy several hours. The transformation seems also to be impeded by the presence of small quantities of foreign matter ; in any case the extent of the transformation varies considerably in different samples of metal, and may even be altogether absent, as in the case of the sample of copper alloyed with 20 per cent. of nickel (Cu-Ni 20 to 100), the resistance of which was given at the beginning of this note.

The following figures relate to three samples chosen from among a dozen that were tested :—

	0.	200.	300.	400.	500.	700.	900.
Cu 50 ...	0.465	0.480	0.505	0.520	0.518	0.530	0.552
Ni 24 ...	0.495	0.513	0.527	0.525	0.518	0.530	0.552
Zn 25 ...	0.514	0.527	0.537	0.525	0.518	0.530	0.552
Cu 66 ...	0.285	0.308	0.320	0.330	0.338	0.352	0.390
Ni 11 ...	0.485	0.497	0.500	0.492	0.475	0.473	0.492
Zn 22 ...							
Cu 81 ...							
Ni 18 ...							

The first of these alloys showed the most marked transformation. The three series of measurements were taken from the heating of specimens cooled at different degrees of rapidity, and consequently unequally tempered.

These experiments give the reason of the fact, already observed, that standard resistances of German silver change in course of time ; the magnitude of their resistance increases. This is because the wires employed are always partially tempered, and become annealed spontaneously under the influence of slight variations of temperature, of mechanical action, or even of the weather merely. We observe with wires of tempered steel a similar spontaneous annealing action, which is shown by a variation of resistance of a contrary sign.

In conclusion, I will give a table of the results obtained with alloys of iron and nickel. Certain of these alloys show, on being heated and cooled, different

Percentage of nickel.	Temperature.	0	200	400	600	800	1000	Points of transformation.
5	{ Rising	0.36	0.45	0.59	0.90	1.38	1.50	680° and 830°
	{ Falling	0.36	0.54	0.77	1.35	1.45	1.50	600°
25	{ Rising	0.98	1.15	1.30	1.42	1.51	1.55	none
	{ Falling	0.98	0.81	1.10	1.42	1.51	1.55	550°
35	Rising and falling	0.59	0.84	1.04	1.10	1.13	1.18	400°
50	Rising and falling	0.46	0.80	1.14	1.28	1.32	1.36	460°

resistances, *i.e.*, the transformations produced by the elevation of temperature are not immediately reversible; they do not take place when the temperature falls again until it is nearly same as the surrounding atmosphere.

It will be observed that iron, nickel and their alloys show at temperatures above the transformation point, a law of variation of electrical resistance which is analogous to that of platinum and its alloys. At lower temperatures, on the contrary, the rate of variation is infinitely more rapid.

### THE ELECTRIC LIGHTING, &c., OF BRUSSELS.

THE following report on electricity has just been issued by the authorities of Brussels:—The question of the electric lighting of the city has not yet received a solution. The offers made after the publication of the particulars last year by the council, gave rise to a serious discussion of the subject by the electricity committee. It was recognised that it was not advantageous to give attention to one or other of these offers any more than to those which had been made previously. It was consequently resolved to again ask for tenders, by indicating, in a detailed specification, the conditions it was thought advisable to impose on the concessionaries. If the offers are not regarded as more favourable than the former, the committee will propose the establishment of the electric light by the administration. The new propositions, which were to be sent in by August 1st last, are now under examination. The small electricity station used for the lighting of the Theatre de la Monnaie, the Hôtel de Ville, and the Grand Place, continued to work with the city's staff.

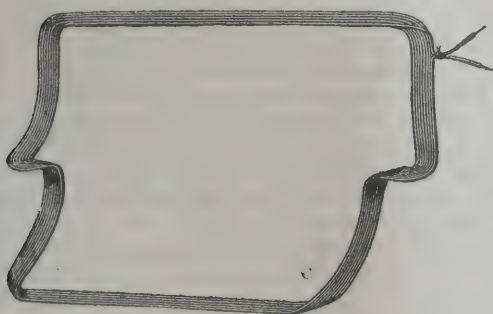

FIG. 1.

The lighting of the theatre had been uninterrupted. Numerous incidents, however, had arisen in the service of charging the accumulators. They had been obliged to raise the conductor cables placed in hooks in the collecting sewers, and fix them on insulators against the vault; and also, after several repairs of the armatures of the dynamos, the fear of an interruption of the lighting caused the ordering of a new armature. The masonry of the boiler has been replaced and braced. The 20-kilo. accumulators have done good service, and are still in good condition. Inside the theatre alterations have been made to facilitate the playing of an organ, which gave rise to some complaints during the season. The arc lamps, used to project the light on the stage, are now fed by accumulators. For the convenience of the staff, a telephone has been constructed between the theatre and the King's house. The electrical distribution in the Hôtel de Ville has been extended to the sheriff's rooms and to the archives office. An accident which happened recently to one of the provisional masts on the Grand Place, determined the authorities to order the execution of definite supports for the electric lamps which light the place. The communal telegraph service has been improved by the adoption of automatic apparatus in connection with the receivers, and by the establishment of a second apparatus in four divisions of police. In order to improve the service, notably as regards clocks, it was necessary to avoid con-

tact with the telephone wires by placing the wires underground; but the expense would be too great. As to lightning conductors, which continued to increase, the report gives as a proof of their utility, that during the violent storm of May 18th last, the lightning had struck several points of the outskirts, but nowhere in Brussels itself. The lightning conductors on the telegraph and telephone lines, however, showed numerous traces of the passage of the electric fluid.

### EICKEMEYER WINDING FOR ELECTRIC RAILWAY MOTOR ARMATURES.

A NEW departure, says the New York *Electrical Engineer*, has recently been made by the Edison General Electric Company in its electric railway work by the introduction upon its motors of the Eickemeyer method of armature winding, whose use it controls in that class of work. As our readers are aware, the armatures of electric railway motors have generally been wound upon the Siemens system, the main objection to which is that the irregular mass of wire at the end has a tendency to move, abrading the insulation and leading to a short circuit. As the burn out most frequently occurs in the under or inner coils, repairs are unduly expensive.

In the Eickemeyer system of winding, each armature coil, fig. 1, is wound upon a form of peculiar construction, and comes out standard and interchangeable in every respect. In building an armature originally, the laminated iron core is first prepared as in the Siemens armature, and upon this are loosely placed the necessary number of standard coils, which are locked

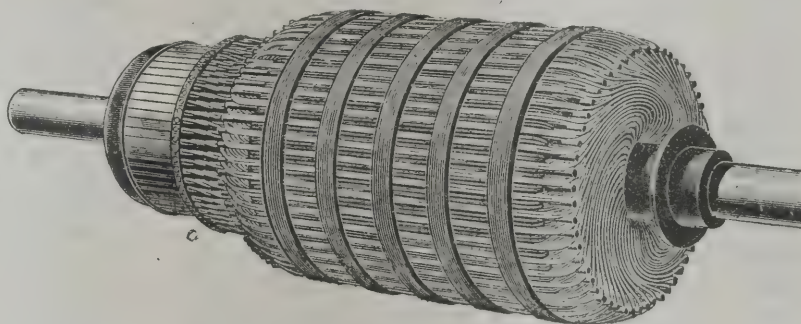

FIG. 2.

in place around the armature by means of the wooden pegs, shown in fig. 2. The result is, a square end both front and rear, instead of the cone-shaped end of the Siemens armature. The coils are held firmly in place, with absolutely no chance for motion, and there is no mechanical pressure from coil to coil which would tend to cause short circuit. The armatures are necessarily of standard diameter and interchangeable, and it is claimed that the Eickemeyer armature will never burn out except from dead over load causing melting of the wire, from accidental mechanical injuries, or from short circuit due to outside causes. If, however, an armature coil should burn out from any of the causes mentioned, it could be replaced without difficulty by any ordinary mechanic and without return to the factory, the whole operation consuming about a day's time and a small amount of material. The local railway company would be provided with a sufficient number of standard coils held in reserve.

Fig. 2 shows the peculiar curvature of the coils at the rear. The same curvature is found at the front end. The whole armature is perfectly ventilated, particularly at the front, where difficulty has frequently occurred. It is the strong belief of the Edison Company that one of the most serious difficulties that has been met with in electric railway work is entirely overcome by this new type of armature they are now manufacturing and using.

## THE PRESENT POSITION OF POSTAL TELEGRAPH CLERKS.

DEVOUTLY as the telegraph clerks may desire to put a period to the admittedly necessary remedial campaign which they have carried on for so many years, and satisfactory as the prospect of an equitable settlement of their claims would be to themselves and the public generally, yet it must be evident to all who have followed the subject recently that there is little or no prospect of an immediate closing of the gates of the telegraphic Temple of Janus. The hindrances to this desired end are not difficult to localise, involved as they are in the Postmaster-General's new scheme, and while for a time the rank and file of many of the postal telegraph clerks' battalions may be resting in the enjoyment of such successes as have already been gained, the results of Saturday's conference in Liverpool indicate that victory has not been gained at all points of the field, that it is not general "along the line," and that much has still to be done before the reasonable, and even modest programme, put forward as the sum total of a telegraph clerk's professional claims, receives official recognition.

There may ensue a brief season of comparative rest, when what we will call the "minor tactics" of the forces will probably be reorganised, when those already wearied with the excitement and anxiety of the strife, its many changes and its varied incidents, will recruit their nervous forces and gain rest for the mind.

No one who has not taken part in commercial or social reforms and movements of a similar nature can adequately realise what wear and tear they demand from the mental and vital forces of the human system. In the case of civil servants, an additional strain is enforced on the individual acting, for instance, on an executive committee. He has to display unwearied devotion to his official duty, being careful not to compromise his conduct officially, and at the same time prove not only to his colleagues but also to those in authority over him that his sincerity and his courage are equal to his professional zeal. We have known a rash or hasty step beyond a certain and often an unknown point to result in disaster to the cause, and reduction or dismissal to the individual.

Many of our readers will have read in the wonderful Italian campaigns of Napoleon of the way in which he ordered brigades and battalions, even in the heat of battle, to take what may appositely be called "hurried rests."

How beneficial these rests were the extent and importance of the little Corsican's many victories sufficiently attest. A brief period of tranquility will act, therefore, as a healthy stimulus to further action, and when the telegraph clerks resume their movement they will be more than ever hopeful of gaining those further concessions which they urge will effect a general settlement of their case.

Having referred to the position of the agitation in a military spirit, it does not follow that we are anxious to see further operations carried out in a bellicose fashion; our counsel has ever been in favour of rational and reasonable methods, and few will deny that the telegraph clerks have been uniformly orderly and businesslike.

Upon the whole, the Postmaster-General has approximated his subject fairly well. In clearing off arrears of long standing in such matters as overtime, bank holidays, and an instalment of justice with regard to sick-pay, he well merits the vote of thanks passed most loyally by the Liverpool Conference.

In the matter of increase of salary, he has not been quite so successful. He has stopped short where he was earnestly asked to effect his greatest reform; we refer now to the retention of the old system of classification. Whether this is the outcome of that official advice which he has considered so necessary, and which he has so highly praised, or the indication of doubt and hesitation on his own part is not very certain; on mature consideration we are inclined to think that it is due to the former cause,

The service cries aloud for a progressive system, such as exists in the Savings Bank, the Intelligence Department, the Receiver and Accountant-General's office, and in other departments. The old anomalies will, unless determined agitation be maintained, once more appear; in fact they are still existent.

In judging matters from the classification platform, we ask why such a glaring injustice should be perpetrated as the increasing of the maximum pay of every class in the service *excepting that of the Senior Class of Telegraph Clerks at the Central Telegraph Department*, which has been either studiously and purposely overlooked, or has been treated with entire indifference. As a representative class from which administrative officers are elected, it stands in a worse position now than it did twelve months ago. It must not be forgotten that the grievances complained of are common to all sections of telegraph clerks.

The clerks in this senior class do the duties of superior officials when occasion requires, but no consideration of any kind has been given to them, though they have as good a claim as any other class in the service. The Postmaster-General has admitted in the House of Commons that senior clerks have to perform the duties of assistant superintendents which involves control of staff, arrangement duties, technical and practical knowledge of telegraphy, adjustment of instruments and circuits, &c. Yet the new scheme contains absolutely nothing for them.

Can it be wondered, then, that there is dissatisfaction with classification. Another point, and one almost as glaring, though of a slightly different nature is, that telegraph clerks in receipt of £160 will no longer receive a month's leave annually, though until the introduction of the Postmaster-General's scheme every one in receipt of £150 per annum, or in a class going to that figure, was entitled to a calendar month's leave each year, and this is notified to the Post Office *employés* in what is known as the "Official Circular." Then, again, the method of awarding sick-pay is very unsatisfactory to the staff in general.

We have shown conclusively that the obstacles in the way of a complete settlement of the telegraph clerks case are those which have been either retained or raised by the Postmaster-General, and probably his advisers.

This is all the more to be regretted, as the Postmaster-General is quite within easy range of bringing affairs to a satisfactory conclusion. In addition to this, he gave to the deputations which waited on him early in the year such an impression of high-minded courtesy, consideration, and even personal sympathy, that such flaws and discrepancies in the new scheme, of which the Postmaster-General has publicly claimed a large constructive share, seem altogether at variance with the close and careful attention he devoted to these subjects when originally presented to him.

It would not be right in this case to blame the Treasury officials for any shortcomings in connection with the scheme, for not so very long since, with a dejected air of injured innocence, one of the Treasury officials in the House of Commons avowed meekly that it was not right to blame the Treasury Lords for being parsimonious or inconsiderate; indeed, such was not the case, and especially with regard to the Post Office, they had, indeed, granted every requisition that had been made on them by the Postmaster-General, they having only in view the commercial prosperity of the department and the best interests of the community. This lets a good deal of side light in on the conjuring done in the name of the Treasury, and may confirm the opinion held by well informed people that the Treasury is made the scapegoat of our modern constitutional government.

The speeches delivered at the Liverpool Telegraph Conference were carefully taken down by the "official reporter," who was present under protest, his intrusion being regarded as illegal; the Postmaster-General will therefore, in due course, find out for himself how near he has been to the point at which a general and satisfactory settlement would have been reached, and which many will regret is still left to the future.

## THE TELPHER AND ELECTRIC RAILWAYS OF THE EDINBURGH EXHIBITION.\*

By E. MANVILLE, M.I.E.E., and J. G. STATTER, A.M.I.C.E.

It may be said truly of the United Kingdom that its inhabitants are, as a whole, very slow in taking advantage of new applications of the forces of nature; and in no instance, perhaps, is this more so than in the application of electricity to traction. When at last, however, they have taken up a new application, they develop it more thoroughly than other nations.

In a paper on "Electric Traction," read by Mr. Bennett before the East of Scotland Engineering Association last year, he observed that whilst there were but few lines of electric tramway in operation in the United Kingdom, not one of these existed in Scotland. The same condition of affairs pertained at the commencement of this year when, through the enterprise of the council of this exhibition, Scotchmen are enabled to see two examples of the application of electricity to traction at work in their capital.

One of these—the telpherage system—is mainly the invention of the late Prof. Fleming Jenkin, who developed his ideas in the University of Edinburgh, and therefore this—the first telpher line erected in Scotland—should be especially interesting to you; the other—an electric tramway, worked from overhead conductors—is the first tramway completely worked by this method in the United Kingdom, and this paper is particularly descriptive of these two systems.

### TELPHERAGE.

Telpherage is a distinct and special application of electricity to traction particularly suitable for the carriage of goods over rough country where the cost of railways is too great. We do not suppose that it is likely to compete with heavy railways, but it is especially applicable to replace heavy cartage where the cost of transport frequently reaches 1s. per ton mile, which is many times the cost of carrying the same quantity on a telpher line.

Light railways have up to the present time been generally erected to supersede the primitive method of carting when the quantities to be carried reach from 100 to 500 tons per diem. The cost of a light railway where bridges, embankments, and cuttings have to be made is considerable, and far in excess of the cost of a telpher line over the same country. A telpher line spans rivers, crosses roads, bridges, valleys, and generally accommodates itself to the smoothing out of excessive gradients caused by the rough surface of the country, and even when the whole line is erected over a country continually rising from end to end of the line, the telpher locomotive can with facility be made to haul loads up gradients that are quite impracticable on an ordinary railway.

Ingenuous devices were invented by the late Prof. F. Jenkin, and brought into practical use, to enable the train to travel automatically without any driver to control it, and a telpher train so equipped goes along the level and ascends gradients and descends gradients at approximately the same speeds, and with a delicacy of regulation that it would be hard to attain in driving a train by hand.

It is the essential idea of telpherage that, instead of carrying heavy unit loads as in a railway and running but few trains a day to do the work, the unit loads carried should be small and the trains should follow each other frequently. As the trains move across miles of country unattended by a driver, and as the speed of any one train might be greater than that of the one in front, it is necessary to have a system of blocking that shall be absolutely certain, and here electricity lends itself splendidly to the object to be achieved.

With a steam locomotive, the most that can be done to stop it is to shut off the steam from the cylinders, but in an electric locomotive it is possible, so to speak, to remove the fire from the fire-box and the steam from the boiler, leaving the locomotive perfectly inert, and in arranging a block system on a telpher line the train in front is arranged to completely cut off the current from the section behind it, so that if the next train should run into this section it immediately loses all power of proceeding until the train in front has moved into a section further on; and thus all possibility of accidents by collision are completely removed.

The telpher line in the grounds of the exhibition measures about 430 yards all round. It is thus necessarily short owing to the space placed at the disposal of the Electrical Engineering Corporation, and does not meet in this short length with all the conditions that exist on lines of greater length and passing over various obstacles, and we therefore propose to describe to you a line recently constructed in Cornwall, which measures nearly three miles all round, and which, passing over country of a difficult nature, involves almost all the conditions that could possibly be met with in telpherage, and the construction of which along its main length is identical with that in the exhibition.

Its use is to convey tin ore from the mine of the Eastpool Tin Company to its stamps. As with the line in the exhibition, it starts with a loop of rigid rail supported in spans of 15 feet, each end of the loop being connected with the up and down flexible lines.

The height of the posts in the mine yard is such that the skeps or buckets which carry the ore only just clear the ground, and are, therefore, in a convenient position for the ore to be shovelled straight into them from the dressing floor. The train, when loaded, proceeds round the loop, passing over buildings in the mine yard and over the boundary walls into the open country, where the line becomes flexible. The posts are here of such a height that the bottoms of the skeps are about 15 feet from the ground, and the whole line ascends a gradient of 1 in 80. Some little distance from the mine yard a curve is reached, and the train leaves the cable to round the curve upon a rigid rail. Shortly afterwards the line crosses a road and then bridges a valley, where the posts rise to a height of nearly 70 feet, maintaining the same gradient and passing directly over the buildings of an ore dressing works and over the end of a row of two-storeyed houses.

After crossing the valley the height of the posts decreases again to about the same height as before, and the second curve is rounded, two more roads being crossed. The line now commences to descend a gradient of 1 in 33 until it reaches a spot rather more than half-way down. Here occurs an abrupt curve, almost a right angle, necessitating the train again leaving the flexible cable and rounding the curve upon a rigid rail. Advantage is taken of this sharp curve to divide the cables and hang requisite ropes upon their ends so as to maintain a constant tension.

Immediately after leaving the compensators the line crosses the high road from London to Penzance, and commences to descend a long gradient of 1 in 26.6. This gradient only ends when the Tolvaddon stamps are reached, where the flexible line terminates, and the train again travels on a rigid rail forming the loop joining the up and down lines at this end. On this loop the train passes the two engine-houses which drives the batteries of stamps, and the skeps are arranged to automatically tip their contents, without stopping, into the receiving hoppers of the stamps.

The engine-houses are fitted with the old type of Cornish engine, in which the beam projects from the engine-house and turns a long crankshaft through a connecting rod about 21 feet in length, and the telpher train passes right over the bob of the engine in the first house at a height of 40 feet from the ground and wends its way beneath the bob of the second engine between the connecting rod and the pump rod. Immediately after the second engine-house the return flexible cable is reached, and the train now travels back empty up the gradient of 1 in 26.6 to the mine yard, where it is reloaded.

The posts supporting the line are constructed in the same manner as those in the exhibition grounds, and consist of two stout baulks of timber, 9 inches by 9 inches, securely bolted and doweled together and bedded to a considerable depth in the ground, and to these are attached the arms which support the cables. These arms consist of a wrought iron strap with a cast iron strut, one on each side of the post, and where the line is flexible are arranged to swing. This is rendered necessary by the movement in the rope caused by the compensation weights referred to later on; and the saddles to which the cables are directly attached are placed at the extremities of these arms and arranged to rock up and down to enable the train to easily pass over them, and also to swivel in a lateral direction to remain parallel with the rope, notwithstanding the movement caused in the arms by the compensation weights.

As it is necessary not to impede the movement of the ropes produced by the compensation weights when passing round a curve, an arrangement is made for the cables to pass through a junction saddle, so shaped as to allow the train to easily pass from the cable to the rigid rail, the cables then rounding the curve and being kept clear of the rail and other obstructions by the horizontal pulleys shown, passing again away from the rigid rail by means of similar junction saddles. These junction saddles are so designed that the cable is free to move through them, at the same time being firmly supported when the train passes from the cable to the rail.

An arrangement of compensation weights and junction saddles enables the rope to move under the rail, and are much the same as those just referred to. But the cables are ended here and pass over pulleys of larger diameter, and have hung on their ends respectively a weight of about six tons on the side which carries the loaded train, and a weight of about four tons on the side which carries the light train.

The rolling stock for this line consists of three trains, each one carrying five tons of ore. Each consists of 20 skeps, each of a capacity of a quarter of a ton, and two locomotives of about 3 H.P. each. As will be obvious, the rope sags as the train passes in between the posts, and the amount of sag produced by the weight of the train with the compensation weights hung upon the end of the cable is about 4 feet per span on the loaded side, and 5 feet per span on the light side, the spans being about 100 feet. The locomotives are so spaced that one locomotive is always descending a sag whilst the other locomotive is ascending a sag. The same is true of the skeps, so that the train is to all intents and purposes balanced throughout its length, notwithstanding the inclines on the cables over which it passes.

The locomotives are almost exactly similar in construction to those used on the exhibition line. They consist of a framework above the line carrying the driving wheels. From this framework is suspended beneath the line a platform carrying the motor, and the motor is connected through a countershaft by a pitch chain with the driving wheels on the framework above, and the platform containing the motor and gear is so arranged as to swing from the framework above without altering the relative positions of the driving chains and wheels. This is a point of considerable im-

\* Paper read at the Edinburgh International Exhibition, before the Royal Scottish Society of Arts.

portance in enabling the locomotives to pass over the sharp incline at the post heads without either of its driving wheels losing grip of the rope.

The countershaft to which the motor is geared carries a special form of centrifugal governor devised by Prof. Fleeming Jenkin, and which automatically cuts off the current from the train when it is proceeding at too great a speed, re-establishing the circuit when the speed has fallen again to the normal.

On the end of the motor spindle is carried a centrifugal brake, which comes into action after the governor has cut off the current and the speed still increases. This is also a design of Prof. Fleeming Jenkin, and we believe we are correct in stating it is the first centrifugal automatic brake ever brought into practical use. It is perfectly reliable, and the loaded trains descend the gradient of 1 in 26.6 by its aid with perfect safety.

The driving wheels of the locomotive are arranged with renewable grooved tyres of a V-shape, which gives an adhesion to the locomotive of about 900 lbs. per ton.

The current is supplied to the line at a difference of potential of about 200 volts. As in the exhibition line, the cables form a return path for the current, a conductor supported on mica insulators carrying the current to the motors, and a small shoe resting on the conductor, and towed along by each locomotive, collects the current.

The duty of the line is about 250 tons per day of 10 to 11 hours working.

The facility with which the curves are rounded will, we believe, commend itself to engineers, and is a distinct advance over a hauling rope aerial railway, at every curve of which a man has to be stationed to push each skip round the rigid rail until it reaches the moving rope again.

This description has purposely been kept as non-technical as possible. That Scotland offers a wide field for the use of telerphage cannot be doubted, and we think we cannot do better than conclude this part of the paper by quoting from Mr. Bennett's paper referred to before, in which he says, "It is only necessary to cast a casual glance at the map of Scotland to perceive that one of its leading characteristics is the absence of railways. Vast tracts of fertile country in Haddington, Berwick, Selkirk, Roxburgh, Peebles, not to mention the more northern counties like Argyll and Inverness, are so many miles from the nearest railway that farmers and other producers are handicapped by the dearth of communication. They cannot compete in the market with rivals more favourably situated on one or other of the existing lines. It would certainly not pay to open up most of these districts, even if a single track and light engine were employed, but they might use telerphage lines laid over the public roads, or close beside them."

#### THE ELECTRIC RAILWAY.

It is not too much to state that the attention of the civilised countries of the world at the present moment is directed to the advance of electric traction as applied to tramways, due to the phenomenal development it has achieved in the United States.

But a few years since there were only a few lines of electric tramway in the States, and these altogether experimental lines. At the same period there were over 5,000 miles of horse tramway, and over 100 miles of cable tramway in operation in the United States. To-day there are about 2,000 miles of horse tramway in the States, over 200 miles of cable tramway, and no less than 2,000 odd miles of electric tramway.

In *Duncan's Tramway Manual* for 1890 will be found a statement that the total mileage of the lines opened to traffic in the United Kingdom at the end of 1889 was 940 miles; therefore, the mileage of electrical tramways in the States exceeds the total mileage of all the tramways in the United Kingdom by more than 100 per cent.

To us in this country it is difficult to conceive how three or four companies could have turned out of their factories and set to work such an enormous amount of electrical plant as this represents in so short a time. Evidently, instead of using their time in persuading tramway companies to have their lines worked by electricity, they have devoted all their time to executing orders which must literally have been poured in upon them by the tramway companies.

The large mileage thus being worked in America enables us to form a judgment beyond question as to the cost of operating electrical tramways from fixed conductors, either overhead or underground, and we may take the figure of 3d. per car mile as the total amount for traction; and in the cases of large systems it is certain that this figure would be even less.

Now, the total amount of capital invested in tramways in the United Kingdom is about £14,000,000 sterling, and the average cost of horse traction is certainly above 5d. per car mile. It is, therefore, obvious that an average saving of at least 2d. per car mile would be achieved were the tramway systems in the United Kingdom worked electrically. The total number of car miles run during the year ending June 30th, 1889, in the United Kingdom was 62,000,000, and the saving of 2d. per car mile in the working expenses would represent a sum of over £500,000, which would be a substantial addition to the dividends now paid on the capital invested in tramways.

Surely figures of this kind must appeal to those shareholders who have subscribed this large amount of capital, and who would, immediately their tramways were worked electrically, earn this extra dividend; and if tramway directors are slow of themselves in adopting this successful and economical method of propelling their

tramcars, it should be the duty of the shareholders in their own interests to stimulate them to its adoption.

There are, roughly, three methods in which electric tramways may be operated electrically: 1. With conductors supported overhead on poles or wires, as with the line in the exhibition. 2. Conductors laid under the road surface in a conduit. 3. Without conductors at all, the energy being derived from accumulators carried within the car itself.

The first two systems derive their energy at all points of the line from a generating station containing the boilers, engines, and dynamos, or, if there should be water power in the neighbourhood of the tramway, from turbines and dynamos, and these must be kept constantly running as long as the tramcars are in motion. In the third method there is a generating station as before, but the current generated therein, instead of being conveyed direct to the cars by conductors radiating from the station, it is utilised for the charging of batteries of accumulators which are carried by the cars; and the cars, therefore, are not dependent for their motion upon the continuous running of the machinery in the generating station. This, coupled with the fact that the cars can run on any line without alteration to the track—assuming it is strong enough to bear the weight—constitutes the advantage of this system, which, however, cannot at all compare in cost of maintenance with the direct conductor method, and, therefore, will not be dealt with in this paper.

The first method with conductors suspended overhead is the method adopted by an overwhelming large percentage of the electrical tramways in existence. A bare conductor of silicium bronze is suspended overhead, either directly from a bracket attached to a post, if the track runs by the side of the road, or from a cross suspension wire stretched between two posts on either side of the road if the track runs in the centre of the road. This conductor of silicium bronze is insulated from the bracket or from the cross suspension wire, by means of an insulator composed almost entirely of mica, and much stronger and better adapted for the work than an ordinary porcelain insulator.

The size of this bare conductor, or trolley wire, as it is more usually termed, may be any size from No. 6 to No. 2 S.W.G.; and if the length of the tramway and the number of cars running upon it is such that the conductivity of the larger size wire would be too small, another insulated cable is run along the posts supporting the brackets or suspension wires, and tapped at intervals into the bare conductor or trolley wire to reduce its total resistance.

Where turn-outs or crossings occur, points and crossings—of much the same description as those used on the tramway lines underneath—are provided, but, of course, are inverted.

The current is collected from the trolley wire by means of a long, light, and strong swivelling arm mounted on the car roof, at the end of which is either a small wheel or a sliding shoe. The wheel or shoe is kept pressed against the bare conductor overhead by a spring or weight at the other end of the swivelling arm, and this method of maintaining contact with the overhead conductor leaves nothing to be desired in practice. It matters hardly at all how rough the track may be, the collecting shoe remains pressed against the conductor with a pertinacity that is quite phenomenal, and it hardly ever leaves the trolley wire.

The silicium bronze trolley wire being of a very hard nature, and the rubbing surface of the contact shoe or contact wheel being soft, the trolley wire itself hardly wears at all, all the wear being on the sliding shoe or wheel, and these are provided with renewable tyres, which cost but little, and, indeed, the total cost of the wear and tear between an overhead conductor and the sliding shoe or wheel is so little that it is hardly calculable per car mile run.

The City of Boston is supposed to be one of the finest architecturally in the United States, and at the present moment the whole of the tramways of the City of Boston—one of the largest tramway systems in any one town of the world—is being fitted up with overhead conductors. Surely, if there is no objection in a large city like this to the use of overhead conductors under these conditions, in this country there must be numerous opportunities, at least in smaller towns and country lines, for utilising the same simple and efficient method of conducting the current to electric tramcars.

No doubt it requires but the introduction of a few such lines substantially erected to overcome the prejudice of local authorities to the use of overhead conductors.

In the larger towns, however, there is no likelihood of the authorities ever permitting the use of overhead conductors, and then the choice is limited to the use of either the accumulator system or the second method mentioned—viz., conductors laid under the road surface. We do not believe that with the present large depreciation upon accumulator cells this method will find favour with most tramway conductors, and that, therefore, the underground system is destined to be that ultimately used in our larger cities.

Of late there have been advocated several systems in which a closed conduit is used containing a conductor insulated from the earth and brought temporarily into contact with a surface rail divided into sections, as the car passes over these sections. This plan has not, however, been yet brought into operation on any practical scale, and we believe that although such a system might be made to work on a small scale under favourable conditions, it is improbable that with the very unfavourable electrical conditions of an ordinary road, this system could be relied upon for constant satisfactory working.

In the other or open conduit system two methods of constructing the conduit itself, as apart from the electrical fittings it contains, may be used. The first consists of building a conduit

between the two track rails and having upon the surface of the road a slot formed by two rails laid flush with the pavement, and introducing an extra amount of metal in the road, which is more or less objectionable to the local authorities. In March of last year, however, an electrical tramway at Northfleet was opened, in which for the first time the conduit was built underneath one of the running rails, the car wheels on one side travelling on one of the rails forming the slot of the conduit itself. This method of construction meets the objections of the local authorities, as it does not in any way add to the amount of metal placed upon the road surface.

Of open conduit systems with continuous conductors several have been tried without success. The objection to those tried so far, however, has been that the conductor is buried in the conduit, and cannot be got at without ripping open the conduit itself, and, as the size of the conduit must necessarily be small to keep the cost of construction to as low a figure as possible, very imperfect insulators are provided for supporting the conductors within the conduit, and these cannot be got at with facility for cleaning purposes. As a result the insulation is very imperfect and considerable leakage of current usually follows, and any repairs to the conductor necessitates a stoppage of the tramway and a taking up of the road.

To ensure an absolutely reliable open conduit system it is essential (1) that all the electrical fittings should be so designed that they can be placed in position or removed for the purposes of renewal without disturbing the road surface, and they must at all times be easy of access; (2) to ensure good insulation the supports should be as infrequent as possible, and where requisite they should be insulated from the rail by means of efficient insulators; (3) rigid collecting arms should be employed to ensure absolute accuracy of travel, to prevent any risk of contact being broken, and to dispense with points and crossings on the conductor; (4) all the devices used, either electrical or mechanical, must be very simple and cheap.

What is now known as the Waller-Manville system of conduits has been designed with a view to embody all these important considerations. In this system is employed a flexible conductor sufficiently small to admit of its being placed in or withdrawn through the slot. The conductor being flexible, the supports can be at long intervals, such as 30 feet, and can therefore be placed in side openings to the conduit and not in the conduit itself. By this means space is provided for large and efficient insulators. Removable covers are provided to these side openings, or hatchways, giving ready access to the insulators. The insulators are mounted in such a manner that, on removing the cover, they can be at once lifted out.

The collecting arm is so designed that the shank can be withdrawn through the slot, and the collector proper through any hatchway.

Under ordinary conditions the conductor simply rests on supporting arms without being attached thereto. When it is necessary to firmly attach the conductor to its support, as, for instance, on sharp curves, absolute flexibility is still maintained, as the supports are so designed that, whilst rigidly resisting either a longitudinal or lateral strain, the same freedom of upward movement is allowed, as in the case of the conductor itself when unattached.

Simple automatic apparatus is provided at intervals to maintain a constant strain upon the conductor, and to prevent sagging too much between the supports.

The current is collected by means of a U-shaped collector, or shoe, in which the conductor runs, the collector lifting the conductor off the ordinary supports during its travel, and in the case of the supports to which the conductor is attached lifting the support itself.

The conductor rests upon the collecting shoe, which passes clear of the supporting arm of the insulator, allowing the conductor when it has passed to fall back again upon the supporting insulator. This method of collection is similar to that which has been described as having proved extremely efficient with the overhead system.

An automatic tension apparatus is so designed that whilst maintaining a constant tension upon the conductor no extra strain or weight is put upon the collecting arm as it passes beneath the apparatus.

It will be seen, then, that whilst all the conditions which are met with in a tramway are fulfilled, the apparatus employed to fulfil these conditions never interferes with the upward flexible movement of the conductor upon which the perfect contact thus obtained depends; also, that no nuts or bolts, or other means of permanently attaching the insulators and their supports to the conduit, are used. Each insulator with its support is complete in itself, and can be removed from the hatchway instantly for cleaning purposes or renewal. The conductor requires the minimum of work to place it in position, as it is but necessary to drop it through the slot along the road to fasten it to the compensating devices and curve devices, and then the mere action of the collecting shoe passing under the conductor the first time places it in position on the supports along the straight parts of the line.

One of the difficulties hitherto encountered with conduit tramways is that of keeping the conduit itself clear of dirt and road debris owing to the obstruction caused by the electrical fittings to the passage of a brush or cleaning device. It will readily be seen that this difficulty does not exist in this system, there being no obstruction to the passage of a brush attached to a car which will sweep the dirt into receptacles provided at the hatch-boxes, from whence it can readily be removed.

Before concluding this paper, we would describe to you the method used on the exhibition tram line for attaching the motors to the tramcars and gearing their armatures up to the car wheels. The same method is used whether the current be supplied from overhead conductors or from underground conductors on a very large percentage of the electrical tram lines now in operation, and experience has proved it to be a very satisfactory method indeed.

The field magnets of the motor are supported in a cradle of gun-metal, which also supports the bearings for the armature and for the countershaft. One end of this cradle terminates in an eye running over a stud supported on a beam carried across the bottom of the car truck, and a flange round the eye rests upon a strong spring; the other end of the cradle terminates in two plumper blocks, which rest directly upon one of the axles of the truck.

The armature is geared to the countershaft by a cast-steel double helical pinion and wheel, and the other end of the countershaft is geared to the car axle by a similar pinion and wheel.

By thus only attaching the motor at one end of the car axle, and allowing it to move to a certain degree radially round the car axle, by supporting at the other end in the way described, great flexibility is obtained, and the effect of the vibrations caused by the wheels travelling over the track and communicated to the motor are thus minimised as far as possible.

Those who are interested in this method of mounting the motor can inspect the arrangement on one of the cars in the grounds, and also any of the other details referred to in this paper.

We have endeavoured to describe to you, in perhaps an imperfect manner, besides the system of telferage, the methods of working electrical tramways through overhead conductors or underground conductors in an open conduit. The subject is one of pressing interest at the present time, and is worthy of treatment at far greater length than is possible within the limits of this paper; and this must be our excuse for making the descriptions as short as possible, and not entering into many details which in themselves are important.

## ELECTRIC LIGHTING REGULATIONS.

MR. COURTNEY BOYLE has forwarded the following copy of regulations issued by the Board of Trade to undertakers under the Electric Lighting Act:—

Regulations and Conditions for securing the safety of the public and for ensuring a proper and sufficient supply of Electrical Energy, made by the Board of Trade under the provisions of the Electric Lighting Acts, 1882 and 1888, and of the Metropolitan Electric Supply Company (West London) Lighting Order, 1889.

### Definitions.

In the following regulations—

The expression "the order" means the Metropolitan Electric Supply Company (West London) Lighting Order, 1889.

The expression "the undertakers" means the undertakers for the purpose of the order.

The expression "consumer" means any body or person supplied or entitled to be supplied with energy by the undertakers.

The expression "consumer's terminals" means the ends of the electric lines situate upon any consumer's premises and belonging to him at which the supply of energy is delivered from the service lines.

The expression "consumer's wires" means any electric lines on a consumer's premises which are connected with the service lines of the undertakers at the consumer's terminals.

The expression "aerial conductor" means any conductor which is placed above ground and in the open air.

The expression "pressure" means the difference of electrical potential between any two conductors through which a supply of energy is given, or between any part of either conductor and the earth; pressure on any alternating current system being taken to be the equivalent of pressure on a continuous current system when it produces an equal heating effect if applied to the ends of a thin stretched wire or carbon filament; and—

(a.) Where the conditions of the supply are such that the pressure cannot at any time exceed 300 volts, if continuous, or the equivalent of 150 volts, if alternating, the supply shall be deemed a low pressure supply;

(b.) Where the conditions of the supply are such that the pressure may exceed the limits of a low pressure supply, but cannot exceed 3,000 volts, or the equivalent of 3,000 volts, whether continuous or alternating, the supply shall be deemed a high pressure supply;

(c.) Where the conditions of the supply are such that the pressure may on either system exceed 3,000 volts, or the equivalent of 3,000 volts, the supply shall be deemed an extra high pressure supply.

Mains, service lines, and other conductors and apparatus are referred to as low pressure, high pressure, and extra high pressure mains, &c., according to the conditions of the supply delivered through the same or particular portion thereof.

Provided that in the case of conductors laid under the surface of the ground in conduits, in accordance with these regulations, and being the property or under the sole charge of the undertakers, low pressure conductor shall mean any conductor in which

the pressure between that conductor and the earth cannot at any time if continuous exceed 300 volts, or, if alternating, 150 volts, or between that conductor and any other conductor laid in the same conduit cannot at any time if continuous exceed 500 volts, or, if alternating, 250 volts.

When any casing, support for conductors, conducting wire or other metallic body is required to be efficiently connected to earth, it shall be deemed to be so connected when it is connected to metallic mains for water supply outside of buildings, or, where these are not available, to a mass of metal having a total surface of at least four square feet, buried to a depth of at least three feet in moist earth, by means of a conductor possessing a mechanical strength, and offering a passage to electrical discharges equal to that of a strand of seven No. 16 galvanised iron wires.

The expression "daily penalty" means a penalty for each day on which any offence is continued after conviction thereof.

All other expressions to which meanings are assigned in the order or principal Act have the same respective meanings in these regulations.

#### I.—REGULATIONS AS TO SAFETY.

##### *General.*

(1.) Save as hereinafter provided, the supply of energy delivered to the consumer's terminals shall be a low pressure supply.

(2.) A high pressure supply shall not be delivered to any consumer's terminals, except for special purposes, and with the approval of the Board of Trade on the joint application of the consumer and the undertakers, and subject to such further regulations as the Board of Trade may from time to time prescribe. But a high pressure supply may be given to distributing or converting stations or points, or to distributing mains, in accordance with the following regulations.

(3.) An extra high pressure supply shall not be given except to distributing stations or other premises in the sole occupation of the undertakers, and with the written consent of the Board of Trade, and subject to such regulations and conditions as the board may prescribe.

##### *Mains and other Conductors.*

(4.) The maximum working current shall not be sufficient to raise the temperature of the conductors or any parts thereof to such an extent as to materially alter the physical condition or specific resistance of the insulating covering, if any, or in any case to raise such temperature to a greater extent than 30° of Fahrenheit's thermometer; and efficient automatic means shall be provided which will render it impossible for this maximum working current by any accident to exceed such limit to the extent of 50 per centum, even for short intervals of time; and special care shall be taken that the cross sectional area and conductivity at joints are sufficient so avoid local heating, and that the joints are protected against corrosion.

(5.) Where any portions of any conductors are exposed in such a position as to be liable to be affected by lightning, they shall be efficiently protected against accident by appliances of such pattern and construction as may from time to time be approved by the Board of Trade.

(6.) Where any high pressure conductors, other than aerial conductors, are placed above the surface of the ground, they shall be completely enclosed in brickwork, masonry, or cement concrete, or in strong metal casing efficiently connected to earth.

(7.) Where any high pressure conductors are laid in subways, or in the same conduits with any low pressure conductors, they shall be completely enclosed in strong metal casing efficiently connected to earth.

(8.) Where any high pressure conductor is laid within a less distance than 18 inches from any low pressure conductor or from the surface of the ground, or where any low pressure conductor is laid within the above-mentioned distance from any previously laid high pressure conductor, efficient means shall be taken to render it impossible that the low pressure conductor or the surface of the ground shall become electrically charged by any leakage from or defect in the high pressure conductor.

(9.) Every high pressure conductor shall be continuously insulated with a durable and efficient material which shall be protected on the outside against injury or removal by abrasion, and every such conductor shall be tested for insulation after having been laid in position and before any joints for service lines are made. The insulation resistance under these conditions shall not be less in any section of the conductor than at the rate 100,000 ohms per mile for every volt of pressure of the supply under a testing pressure of at least 100 volts, and the undertakers shall duly record the results of the tests of each conductor, or section of a conductor, and at all times permit an electric inspector to examine and take copies of such record.

(10.) The insulation resistance of any complete circuit used for high pressure supply, including all devices for producing, consuming, or measuring energy, connected to such circuit, shall be such that should any part of the circuit be put to earth through a resistance of 2,000 ohms, the leakage current shall not exceed 0.04 ampere in the case of continuous currents, or 0.02 ampere in the case of alternating currents. Every such circuit shall be fitted with an instrument of such pattern and construction as may from time to time be approved by the Board of Trade, which shall immediately indicate any defect which may at any time occur in the insulation resistance of either conductor.

Every such circuit shall be tested for insulation at least once in every week, and the undertakers shall duly record the results of

such testings, and at all times permit an electric inspector to examine and take copies of such record.

(11.) In the case of a high pressure supply on any alternating current system, where separately insulated conductors are laid in the same conduit or pass through the same boxes, precautions shall be taken against the discharge of electric sparks between the insulating covering of oppositely charged conductors, by providing a sufficient connection of a conducting nature from one covering to the other throughout.

##### *Conduits.*

(12.) All conduits used as receptacles for conductors shall be constructed of durable material, and of ample strength to resist any pressure due to heavy traffic or other forces to which they may be expected to be subjected.

(13.) Where the conductors in any conduit are not continuously insulated, adequate precautions shall be taken to ensure that no accumulation of water shall take place in any part sufficient to raise the level of the water into contact with the conductors.

(14.) All conduits for conductors constructed in streets in which gas mains are also laid, shall be efficiently protected against an accumulation of gas.

(15.) All street boxes shall be efficiently protected against an accumulation of gas or water, and their covers so secured that they cannot be opened except by means of a special appliance.

##### *Converting Stations.*

(16.) Converting stations, or points in a system of distribution to which a high pressure supply is given from generating stations, and from which a low pressure supply is given to one or more consumers, and which are not on the consumer's premises, shall be established in suitable places, which are in the sole occupation and charge of the undertakers.

(17.) In every case where the supply is transformed at a converting station as described in the preceding regulation, some means or apparatus approved by the Board of Trade shall be provided which shall render it impossible that the low pressure distributing mains shall be at any time charged to a dangerous difference of potential from the earth, owing to any accidental contact with, or leakage from, the high pressure system either within or without the converting station.

##### *Consumer's Premises.*

(18.) Where the general supply of energy is a high pressure supply, and transforming apparatus is installed on the consumer's premises, connected to the distributing mains by high pressure service lines, and to the consumer's terminals by low pressure service lines, the whole of the high pressure service lines, conductors, and apparatus, including the transforming apparatus itself, so far as they shall be on the consumer's premises, shall be completely enclosed in solid walls, or in strong metal casing efficiently connected to earth, and securely fastened throughout.

(19.) In every case where any transforming apparatus is installed on the consumer's premises, as described in the preceding regulation, some means or apparatus approved by the Board of Trade shall be provided, which shall render it impossible that the low pressure service lines and consumer's wires shall be at any time charged to a dangerous difference of potential from the earth, owing to any accidental contact with, or leakage from, the high pressure system either within or without the transformer.

(20.) All terminals, low pressure service lines, or other apparatus, between the transforming apparatus or other source of supply and the consumer's terminals, so far as they shall be on the consumer's premises, shall be completely enclosed in insulating cases or coated with insulating material in such a manner that no part of them can be touched by any person without the removal of such case or coating, and, wherever exposed, shall be efficiently protected against injury to the insulation.

(21.) The undertakers shall be responsible for all electric lines, fittings and apparatus belonging to them, or under their control, which may be upon the consumer's premises being maintained in a safe condition and in all respects fit for supplying energy.

(22.) In delivering the energy to the consumer's terminals the undertakers shall exercise all due precautions so as to avoid risk of causing fire on the premises.

(23.) If the undertakers are reasonably satisfied, after making all proper examination by testing or otherwise, that a connection with the earth exists at some part of a circuit of such resistance as to be a source of danger, and that such connection does not exist at any part of the circuit belonging to the undertakers, then and in any such case any officer of the undertakers, and duly authorised by them in writing, may, for the purpose of discovering whether such connection with the earth exists at any part of a circuit within or upon any consumer's premises, at all reasonable times, after giving one hour's notice of his intention to do so, enter any such premises and disconnect the consumer's wires from the service lines, and may require the consumer to permit him to inspect and test the wires and fittings belonging to the consumer and forming part of the circuit.

(24.) If on such testing the officer discovers that a connection exists between the consumer's wires and the earth, and that such connection has an electrical resistance not exceeding 5,000 ohms, or if the consumer does not give all due facilities for such inspection and testing, the undertakers shall forthwith discontinue the supply of energy to the premises in question, giving immediate notice of such discontinuance to the consumer, and shall not recommence such supply until they are reasonably satisfied that such connection with the earth has been removed.

Provided that in cases where the maximum power taken by any consumer exceeds 25,000 watts, the consumer's wires may be divided for the purposes of this testing into separate circuits, the insulation resistance of each of which shall exceed 5,000 ohms.

(25.) If any consumer is dissatisfied with the action of the undertakers either in discontinuing or in not recommencing the supply of energy to his premises, the wires and fittings of such consumer may on his application and payment of the prescribed fee be tested for the existence of connection with the earth by an electric inspector, or if no electric inspector has been appointed, by a person appointed by the Board of Trade.

This regulation shall be indorsed on every notice given under the provisions of the last preceding regulation.

*Regulations as to Aerial Conductors where erected with necessary consents.*

(26.) An aerial conductor shall not in any part thereof be at a less height from the ground than 20 feet, or where it crosses a street, 35 feet, or within 7 feet of any building or erection other than a support for the conductor; except where brought into a building for the purpose of supply.

(27.) Service lines from aerial conductors shall be led as directly as possible to insulators firmly attached to some portion of the consumer's premises which is not accessible to any person without the use of a ladder or other special appliance, and from this point of attachment to the consumer's terminals they shall be enclosed and protected in accordance with the preceding regulations as to service lines on the consumer's premises.

(28.) Every aerial conductor shall be attached to supports at intervals not exceeding 200 feet where the direction of the conductor is straight, or 150 feet where this direction is curved, or where the conductor makes a horizontal angle at the point of support.

(29.) Every support of aerial conductors shall be of a durable material, and properly stayed against forces due to wind pressure, change of direction of the conductors, or unequal lengths of span, and the conductors and suspending wires (if any) shall be securely attached to insulators fixed to the supports. The factor of safety for the conductors and suspending wires shall be at least six and for all other parts of the structure at least 12, taking the maximum possible wind pressure at 50 pounds per square foot. No addition need be made for a possible accumulation of snow.

(30.) Every support, if of metal, shall be efficiently connected to earth, and if of wood or other non-conducting material, shall be protected by a lightning conductor fastened to its support along its entire length, and projecting above the support to a height of at least six inches, such lightning conductor being efficiently connected to earth.

(31.) Where any aerial conductor crosses a street, the angle between such conductor and the direction of the street at the place of such crossing shall not be less than 60°, and the spans shall be as short as possible.

(32.) Where any aerial conductor belonging to the undertakers is erected so as to cross any other aerial conductor or any suspended wire used for purposes other than the supply of energy, precautions shall be taken by the undertakers against the possibility of their conductor coming into contact with such other conductor or wire, or of such other conductor or wire coming into contact with their conductor by breakage or otherwise.

(33.) Every high pressure aerial conductor shall be continually insulated with a durable and efficient material to be approved by the Board of Trade to a thickness of not less than one-tenth part of an inch, and in cases where the extreme difference of potential in the circuit exceeds 2,000 volts, the thickness of insulation shall not be less in inches or parts of an inch than the number obtained by dividing the number expressing the volts by 20,000. This insulation shall be further efficiently protected on the outside against injury or removal by abrasion. If this protection be wholly or partly metallic it shall be efficiently connected to earth.

(34.) The material used for insulating any high pressure aerial conductor shall be such as will not be liable to injurious change of physical structure or condition when exposed to any temperature between the limits of 0° and 150° Fahr., or to contact with the ordinary atmosphere of towns or manufacturing districts.

(35.) Every aerial high pressure conductor shall be efficiently suspended by means of non-metallic ligaments to suspending wires, so that the weight of the conductor does not produce in it any sensible stress in the direction of its length, and the insulated conductors and suspending wires, where attached to supports, shall be in contact only with material of highly insulating quality, and shall be so attached and guarded, that in case they break away it shall not be possible for them to fall away clear of the support.

(36.) The undertakers shall be responsible for the efficiency of every support to which their aerial conductors are attached, and every such support shall be marked to indicate the ownership of the conductor.

(37.) Every aerial conductor belonging to the undertakers, including its supports and all the structural parts and electrical appliances and devices belonging to or connected with it, shall be duly and efficiently supervised and maintained as regards both electrical and mechanical conditions.

(38.) The undertakers shall not permit any aerial conductor to remain erected after it has ceased to be used for the supply of energy, unless they intend within a reasonable time again to take it into use.

*Penalties.*

(39.) If the undertakers make default in complying with any of the preceding regulations they shall be liable to a penalty not exceeding £10 for every such default, and to a daily penalty not exceeding £10.

The imposition of any penalty under this regulation shall not affect the liability of the undertakers to make compensation in respect of any damage or injury which may be caused by reason of such default.

*II.—REGULATIONS AS TO SUPPLY.*

(1.) One week at least before the undertakers are ready to commence to supply energy through any feeding, charging, or distributing mains, they shall serve a notice upon the County Council and the local authority of their intention to commence such supply.

(2.) From and after the time when the undertakers commence to supply energy through any distributing mains, they shall maintain a supply of sufficient power for the use of all the consumers for the time being entitled to be supplied for such main; and such supply shall, except so far as may be otherwise agreed upon from time to time between the County Council and the undertakers, be constantly maintained at such pressure as may be fixed under the provisions of these regulations. Provided that, for the purposes of testing, the authority by whom the electric inspector is appointed may give permission to the undertakers to discontinue the supply at such intervals of time and for such periods as it may think expedient, and that for any other purposes connected with the efficient working of the undertaking, the undertakers may, with the permission of the Board of Trade, discontinue the supply at such intervals of time and for such periods as the Board of Trade may think expedient. Where the supply is so discontinued, notice of such discontinuance, and of the probable duration thereof, shall be forthwith served upon the County Council and the local authority.

(3.) The system of distributing mains shall be so arranged in sections, that in case it becomes necessary to stop the supply through any portion of a main for more than one hour, for the purposes of repairs, or for any other reason, the stoppage of supply will in no case exceed in amount a maximum power of 200,000 watts, or extend to the premises of more than 80 consumers, and in the case of every stoppage for more than one hour, reasonable notice shall be previously given by the undertakers to every consumer affected thereby except in cases of emergency.

(4.) During the whole of the period when a supply of energy is required to be maintained by the undertakers in the distributing mains under the order and these regulations, it shall be maintained at a constant pressure (in these regulations termed "the standard pressure") to be fixed as hereinafter specified; but such standard pressure may be different for different portions of the distributing mains. Provided that the undertakers shall be deemed to have complied with the requirements of this regulation so long as the pressure does not at any point vary more than three per cent. from the corresponding standard pressure in the case of a general supply at low pressure, or two per cent. in the case of a general supply at high pressure, unless changes in pressure recur so frequently as to cause unsteadiness in the supply.

(5.) The standard pressure shall be fixed by the undertakers for every pair of distributing mains, and notice of the amount of such standard pressure shall be given to the County Council before the undertakers commence to supply energy to consumers through such mains, and such standard pressure shall not be altered except by permission of the County Council, and upon such terms and conditions as the County Council may impose, and after public notice has been given during a period of one month, in such manner as the County Council may require, of the intention of the undertakers to apply for permission to alter the same. The undertakers may appeal against any decision of the County Council under this regulation to the Board of Trade, whose decision shall be final.

(6.) Before commencing to give a supply of energy to any consumer, the undertakers shall declare to such consumer the constant pressure at which they propose to supply energy at his terminals. The pressure so declared at any pair of consumer's terminals shall not, except by agreement, be greater than 115 volts or less than 45 volts, if continuous, or the equivalents thereof respectively, if alternating, and shall not at any time be altered or departed from except in consequence of any authorised alteration of the corresponding standard pressure. In distribution on the three-wire system, the central terminal shall for the purposes of this regulation be considered to form a pair with either of the outer terminals, and similarly for multiple-wire systems; and, in the case of a transformation of energy on the consumer's premises, the undertakers shall give the consumer the choice of a supply at either of two different pressures, one of which shall be approximately half the other, and in such case the pressure so chosen by the consumer shall be the declared constant pressure.

(7.) The variation of pressure at any consumer's terminals shall not under any conditions of the supply which the consumer is entitled to receive, nor at any time, exceed 4 per centum from the declared constant pressure, whether such variation be due to the resistance of the service lines or apparatus belonging to the undertakers, or to any action or effect produced by such apparatus, for which the consumer cannot be shown to be responsible, or, partly to any variation of pressure in the distributing mains from which the supply is taken.

(8.) If the undertakers make default in complying with any of

these regulations as to supply, they shall, subject to the provisions of the order, be liable to a penalty not exceeding £5 for every such default, and to a daily penalty not exceeding £5.

These regulations are made subject to the power of the Board of Trade to make such further or other regulations as they may think expedient; and nothing in these regulations shall be construed to authorise the undertakers to lay any electric line or work their undertaking otherwise than in accordance with the order and the principal Act, or to supply energy otherwise than by a system for the time being approved of by the Board of Trade under the order.

### ELIMINATING THE TEMPERATURE ERROR IN VOLTMETERS.

WE read the following in *L'Electrician*:—In all voltmeters based upon electro-magnetic action, the current passing through the bobbin depends on the difference of potential to be measured, and on the resistance of this bobbin. If this resistance is increased by heating, the instrument is retarded, and if when it has been calibrated the heating caused by a given difference of potential producing a continuous current in the bobbin has been taken into account, the voltmeter can only give exact indications on condition that practically the same voltage is always maintained at the terminals. In order to remedy this inconvenience, Dr. Kahle has conceived a method of winding the bobbins of voltmeters, which renders their indications independent of the temperature. This result is obtained by winding the bobbin with two parallel wires, acting in opposite directions. The principal wire magnetises, and the secondary wire demagnetises the core of the voltmeter; but as the auxiliary wire has a greater resistance than the principal wire, the magnetising action predominates. By taking for the principal wire a metal whose coefficient of temperature is higher than that of the secondary wire, we can easily see that a rise in temperature reduces both the magnetising action of the principal circuit and the demagnetising action of the secondary circuit. In order that the resulting electro-magnetic effect may remain the same, it is necessary that the difference between the ampère-turns of the two bobbins should be the same for all temperatures, a result which is obtained when the ratio of the two windings is the same as that of their coefficients of temperature.

It is evidently advantageous to employ for the principal wire a metal of low specific resistance, and for the auxiliary winding one of high specific resistance. As, however, the coefficient of temperature of good conductive metals is generally somewhat high, and that of bad conductors rather too low, the condition indicated above for establishing a system of compensation cannot be fulfilled without an accessory arrangement, which consists in establishing an external resistance, the coefficient of temperature of which is not very high, in series with the principal wire. Dr. Kahle has constructed, on these principles, voltmeters whose indications remain quite independent of the temperature.

**Telephones in New York.**—The Metropolitan Telephone Company of New York has the largest multiple switchboard in the world; it has a capacity of 6,000 metallic circuit subscribers, and at the present time is operating more than 3,800. The average daily number of connections made on this board is 48,238, and the average for the whole city is 103,621, about 98 per cent. of these connections being made between the hours of 8 a.m. and 6 p.m. In one station there are 128 operators, each of whom attends to between four and five hundred calls per day of 10 hours. The underground plant of the company has grown to a wonderful extent. There are in operation at the present time nearly 300 separate underground cables, each containing 50 twisted pairs of conductors, aggregating 145.5 miles of cable, or over 14,000 miles of wire. 140 of the 300 cables terminate at one office.

### LONDON COUNTY COUNCIL.

The weekly meeting was held on Tuesday last at Spring Gardens, with Sir John Lubbock in the chair.

The Highways Committee had considered a notice (Registered No. 119), dated 3rd October, 1890, of the London Electric Supply Corporation, of intention to lay distributing mains in Southwark Street, Blackfriars Road, and Borough High Street (1 plan). There appeared to be no objection to what is proposed, provided that the mains for Southwark Street be laid in the subway there. The committee recommended that the sanction of the council be given to the works referred to in the notice (Registered No. 119) of the London Electric Supply Corporation, dated 3rd October, 1890, upon condition that the company do give two days' notice to the council's engineer before commencing the works; that the mains for Southwark Street be laid and properly protected in the subway there; that the positions to be occupied by the mains in the subway be subject to the approval of the engineer of the council, and that the work of placing them be carried out to his satisfaction; that the mains in the other thoroughfares specified in the notice be laid under the footways, and be kept 9 inches below the underside of the pavement, wherever it is found practicable to do so, and that where the mains cross the carriage-ways, they be kept at the same depth below the concrete, or the road material, as the case may be; that the clerk be instructed to forward to the company a notice requiring it to lay the mains in Southwark Street, referred to in the notice dated 3rd October, 1890 (Registered No. 119), in the subway of that thoroughfare.

It was reported that during the present year testings made with the portable photometer in Bermondsey, Rotherhithe, Deptford, and Greenwich have shown the gas supplied by the South Metropolitan Gas Company in those districts to have been of deficient illuminating power. The testings, with but one exception, have shown the gas supplied to be of a less illuminating power than the company are required by their Act to supply. The nearest official testing stations to the districts in question are at Tooley Street, Peckham, and Plumstead, and it is clear that the large area between these stations is without any effectual check on the quality of the gas supplied. In these circumstances, they have directed the attention of the Gas Referees to the matter, and have requested them to prescribe an additional gas testing place in such a position as to ensure that gas supplied to the district in question is subject to official examination.

The weekly cash paper showed the following items:—

## NOTES.

**Galway Electric Lighting.**—It may be of interest to our readers to know that there are being erected for the Galway Electric Company two 42-inch Hercules turbines giving from 75 to 90 H.P., with a fall of from 9 feet to 11 feet, to supply light and motive power for which there is a demand. The company has, since July 1st, been lighting the docks and other works, making use of an old flour mill machinery.

**Electric Light at Stockholm.**—Although detailed plans for the erection of the proposed electric central station which, like the gas works, is corporation property, have not yet been laid before the corporation, the latter has given permission to start the preparatory work, such as clearing away of old buildings from the site, &c. As usual, the estimated cost is now found to be too low, and the total expenditure will probably be nearer 2,000,000 kr. than 1,500,000 kr., the amount of the original estimate.

**Electric Lighting in Nelson.**—The gas committee of the Nelson local authority have received and approved the report of the gas manager upon a scheme of electric lighting for the town, and he has been instructed to get out specifications for the laying down of a cable, and other necessities, for an installation capable of producing 600 lights. At the last meeting of the board it was stated, in answer to a question, that the price of the electric light would be double that of gas, and while the latter was 2s. 6d. per 1,000 feet, the former would be 4s. 6d. for the same amount of illumination.

**Electric Lighting in Pemberton.**—The members of the Pemberton (Lancashire) Local Board have expressed themselves satisfied with the electric light trials, and the chairman of the board is of opinion the adoption of the system throughout the district is only a question of time.

**The Lineff Traction System.**—Colonel Huber, of the well-known Oerlikon Engineering Works, last week inspected the experimental line on the Lineff system at Chiswick. Negotiations were commenced on behalf of the Oerlikon Company with a view to obtain a license from the Lineff Syndicate for various continental countries. We understand that a powerful combination is to be formed for the purpose of working the invention in France. With regard to the application of the system on the West Metropolitan tramways, we are informed that the Hammersmith Vestry has decided to grant the application, subject to a favourable report being received from an expert whom they will appoint.

**Meters.**—It would be interesting to ascertain how many electricity meters are in use in London. According to a recent return regarding the Geneva Central Station, 450 Aubert meters and 65 Aron meters are in operation; yet the number of incandescent lamps in daily service is only 5,375, of which 2,433 are located in the theatre and the remaining 2,942 are distributed among 216 subscribers. We wonder whether London, with all its central stations, can total 515 meters in use.

**The Tudor Accumulator.**—The use of Tudor accumulators in Germany has been greatly extended during the past few years. So much has this been the case that the makers, Messrs. Müller and Einbeck, of Hagen, resolved to open branch works in Austria, and the accumulator factory of Messrs. Getz and Odendall has just been acquired for that purpose.

**A Long Electric Line.**—An American contemporary says:—A notable installation is about to be made between Seattle and Tacoma, a distance of 42 miles. This will be the longest electric railway in the world.

**The Central Institution Students.**—Of the 100 odd candidates who entered at the end of September for the Matriculation Examination at the City and Guilds Central Institution 60 passed, and 16 did sufficiently well to be allowed to enter the college as unmatriculated students. In addition to the regular students of the second and third years, and the 76 above referred to, who are admitted to attend courses in *all* the four departments of mathematics and mechanics, engineering, physics and chemistry, some 20 special students have entered for portions of the advanced courses in one or more of these departments. On the result of the entrance examination the Clockworkers' Scholarship of £60 a year, with free education, tenable for two years and renewable for a third, was gained by C. E. Stamp, from St. Paul's School, and the three Institute's Scholarships, each of sufficient value to cover the students' fees for three years at the Central Institution were gained by G. H. Baillie, from Winchester House School, C. V. Drysdale from the Finsbury Technical College, and A. E. Sonneborn from Tottenham College. At the end of last session the John Samuel Scholarship, granted to a meritorious student of the Central Institution at the close of his second year's course, and consisting of £30 and free education for the third year, was awarded to C. W. Clinton; the Siemens medal, given to the students of greatest merit in the department of Electrical Engineering, was taken by R. Wightman.

**Faure-Sellon-Voelckmar Cells.**—A well-illustrated pamphlet, which is being distributed by the *Bulletin International de l'Electricité*, has been published by the Société Française d'Accumulateurs Electriques, describing these well-known accumulators (E.P.S. type). Details are given regarding the construction of the cells, their methods of use, applications for lighting or as regulators, and to traction purposes. A perspective view is given of one of the accumulator cars now in service on the Levallois-Madeleine Tramway, which was described in the REVIEW some time ago.

**Priestman's Petroleum Engines.**—We learn that a gold medal for these oil engines has been awarded at the Edinburgh Exhibition.

**Telephony in Scotland.**—The Glasgow Committee of the Mutual Telephones Company, Limited, has decided to adopt the metallic system for Scotland, so as to enable subscribers to speak over long distances, as, for instance, between Glasgow and Manchester and London. The new system is proposed to be inaugurated with the new year.

**A Runaway Electric Car.**—The *Birmingham Post* of the 14th inst. says:—The passengers by the Bristol Road tram, leaving Navigation Street at 7.45 last evening had a very narrow escape. As soon as the car began descending Suffolk Street it was evident that something was wrong, and as the driver kept ringing his bell, and the speed of the tram increased, it became evident that he had lost control of it. The heavily-laden car went down the hill at a fearful pace, and threatened to upset as it passed from the double to the single line. The progress of the car was watched with intense anxiety, as the crossing at the bottom of Holloway Head is a most dangerous one. By the regulations of the company the car should be stopped at the bottom of Suffolk Street, but it was apparent that for some reason or other this was impossible, and a collision with the many vehicles about seemed all but inevitable. Fortunately, however, everything was cleared out of the way, and the tram brought to a standstill by the cabstand, very much to the relief of the occupants. What was the cause of the incident could not be gathered beyond that there was some defect or other with the brake-power. The name of the driver was taken by a police-officer, and the rest of the journey was performed under less exciting circumstances.

**Telephones in Sweden.**—Although the Swedish telephonic system is probably unrivalled, the Swedish engineers evidently do not mean to rest on their laurels. The Swedish Government has placed a sum of 1,600 kr. at the disposal of the State telegraphs, asking them to send a suitable man to Holland, England, and America, in order to see whether any improvement has recently been made in telephones.

**Gold Medal.**—Messrs. Davis and Timmins, of Hatton Garden, have been awarded a gold medal by the jurors of the Edinburgh Exhibition for general excellency of manufactures.

**Literary Announcements.**—Messrs. Crosby, Lockwood & Co. announce a fourth edition of "Electric Light: Its Production and Use," by J. W. Urquhart.

**City and South London Railway.**—The *Financial News* says some of the shareholders in the City and South of London Railway are beginning to ask when their underground electric railway from King William Street to Stockwell will be inaugurated. The chairman of the company has frequently assured them that the line "is expected to be opened shortly," and that most of the machinery and rolling stock is already to be found at the Stockwell depôt. A visit will, however, convince anyone that the railway and plant are not in such a forward condition as would appear from the chairman's statements. As over £650,000 has already been sunk in the undertaking during the past four years, it is quite time the railway was opened.

**Copper.**—Production of copper ore from the mines of the Canadian Copper Company, Sudbury, Ont., for the last year is officially stated to be 60,000 tons. Copper shares are not in a good position, according to the dealings on the French Bourse. The feeling of speculators is that copper shares are going lower.

**The New Cables between Peru and Chili.**—As foreshadowed in our "Notes" of last week, the cable steamer *Silvertown* left Greenhithe, on October 11th, for the West Coast of South America. On the preceding day a large company of guests were invited to luncheon on board, to bid farewell to their friends, and to wish the expedition God-speed. The ship takes out about 1,750 nautical miles of submarine telegraph cable, weighing about 2,700 tons, and the total cargo carried, including coal, cable, provisions, and general stores, weighs somewhat under 5,000 tons, a comparatively light burden for this vessel, whose capacity is nearly 7,000 tons. The cable was manufactured by the Silvertown Company for the Central and South American Telegraph Company, and is to be laid from Chorillos, near Lima, Peru, to Yquique, the well-known nitrate port, and thence to Valparaiso, the principal port of Chili. More direct and rapid communication than now exists will be thus secured between the points mentioned, since the present cables owned by the West Coast of America Telegraph Company, and laid in 1875, touch at many intermediate places along the coast between Lima and Valparaiso. The Central and South American Company, by means of their cables from Lima northwards along the West Coasts of South and Central America, their land line across the isthmus of Tehuantepec, and their cables across the Gulf of Mexico, will, on completion of the new lines, have communication over their own systems from Valparaiso to the United States. The total complement of persons on board amounts to 144, roughly divided into: Staff, officers, and engineers, 23; cable hands, 40; crew, stewards, &c., 59; stokers, firemen, &c., 22. The expedition is under the direction of Mr. M. H. Gray, engineer-in-chief, and Mr. J. R. France accompanies the ship as representative of the Central and South American Telegraph Company. The trip is expected to last between five and six months, including voyages out and home (about 9,000 miles each way), sounding work, cable laying, term of guarantee, and possible delays. We wish the expedition every success.

**Vestries and Electric Mains.**—Major C. B. Waller, the manager and secretary of the London Electric Supply Corporation, was summoned by the Vestry of St. George the Martyr, Southwark, on Wednesday, for that "he did cut away and take out part of a sewer in Union Street, Borough, for the purpose of laying mains for electric lighting without first having obtained the permission of the vestry." The surveyor of the vestry discovered a week or so since that the Corporation had cut away a portion of a sewer for the purpose of carrying their mains over it. For the defendant it was urged that the vestry had no power to interfere, and in the end Mr. Slade adjourned the summons to give both parties an opportunity of referring the matter to the Board of Trade.

**The Popularity of Electrotechnics.**—The total number of students receiving electrical instruction in the Finsbury Technical College (day and evening) to date, this session, is 595, of whom 444 attend laboratory work. If similar Institutes are filled in a like proportion we shall soon have that old question of "What shall we do with our boys" raised again."

**Removal.**—Mr. Carl Oppermann informs us that he has removed his business from 41, Sigdon Road, Hackney, to 2, Wynnatt Street, Clerkenwell, E.C.

**Business Mention.**—Messrs. O. Berend & Co. have shown us some really good designs in electroliers in bronze and majolica; in fact, more tasteful specimens we never saw. The price is said to be very moderate.

**The Pacific Cable.**—We extract the following from the *Evening News* of October 11th: "Sir John Pender, the 'Cable King,' has arranged to pay a visit to the Pacific side of the world next year, and he has already apprised Mr. Sandford Fleming, the Austral-Canadian cable enthusiast, that he will then be prepared to discuss the feasibility of establishing cable-graphic communication between Vancouver and the Antipodes. It is evident from this that Sir John and his colleagues have come round to the point of recognising the necessity for an alternative cable to Australia by way of the Pacific. The fact of the whole matter is, that the Eastern Telegraph Company, true to the national instinct of self-preservation, have realised that if their monopoly of the cable business is to be maintained, they must step in and lay the Pacific cable. The last total interruption of the whole of their cables between here and Australia had the effect of producing a strong feeling in the colonies in favour of the long talked of Pacific cable as an alternative line in case of a recurrence of such accidents, and there can be no doubt that if Sir John Pender and his friends display any tardiness in taking the matter up, somebody else will do the work before long.

**Running Alternators Parallel.**—At a late hour we have received a very interesting letter on this subject from Mr. Hooker, electrician to the Bath Electric Light Works, who has been running Mordey alternators in parallel in a most satisfactory manner. As a drawing accompanies his communication, we must reserve it till next week.

**Sales of Electrical Plant, &c.**—It will be noticed in our business columns that a stock of "Lever" arc lamps and the patent rights for England and abroad are offered for sale. The electrical plant used for lighting the House of Commons is also to be put up to public auction.

**To A. E. M.**—The patent specification in which the form of magnet used in the Gower-Bell telephone receiver is first described, is No. 315, dated 25th January, 1879, and it does not appear that any claim is made in the same for the particular form of magnet and coils used; on the expiry, therefore, of the Bell patent in December, this form of magnet for telephonic purposes becomes public property, though probably this might be contested by the owners of the patent.

**Edinburgh International Exhibition.**—The Royal Scottish Society of Arts held a special session at the Exhibition on October 13th, under the presidency of Lord Kingsburgh. Five papers were read, three of which were electrical, viz., "On the Telegraphic Exhibits," by Prof. Grant-Ogilvie; "Telpherage and Electric Railways," by Mr. E. Manville; and "Electrical Navigation," by Mr. A. R. Bennett. There was a large attendance of members. In moving a vote of thanks to the authors, Lord Kingsburgh regretted that the electrical industries had, so far, met with scant recognition in Scotland, and expressed a hope that the abundant water supplies in the Highlands would soon be turned to useful account in providing light and power to the various cities and towns. The members afterwards took trips on the telpherway and electric tramway and in the electric launches; and a special vote of thanks was accorded to Mr. Bennett, to whose invitation the meeting had been due.

**Steam Pipe Covering.**—Messrs. A. Haacke & Co. have received a silver medal at the Edinburgh Exhibition, where they covered the main steam pipes with their pyrostat composition. This is a non-conducting composition, and can be applied even to red-hot surfaces, and is specially adapted for covering boilers and steam pipes containing 150 to 200 lbs. pressure.

**Electric Lighting.**—The Town Council of Paisley have agreed to apply to the Board of Trade for a provisional order to supply electric lighting for private and public purposes within the burgh.

**Pictorial.**—It is not often our lot to view a combination of things electrical and pictorial; indeed it is generally considered that machinery of any description absolutely refuses to lend itself to any effort of a picturesque nature; but a day or two since we were invited to view a portrait of Mr. Thomas Parker, of Wolverhampton, and promptly responded in person to the invitation. On arriving at the studio of the artist, Mr. E. Goodwyn Lewis, at No. 17, Fitzroy Street, we were surprised to find a fine painting representing not only Mr. Parker but that gentleman surrounded by machinery and electrical instruments, as if in the works at Wolverhampton. Through an open window is well shown and judiciously treated a tram-car, and the electric light is freely displayed, the whole being painted as illuminated by that light. It is an important work, bristling with difficulties, which the artist must be credited with having overcome in a remarkable degree. We may add that the work has been executed for Mr. Oddie, of Ballarat, Australia, who intends presenting it to the Ballarat Art Gallery, art and electricity both being among the donor's favourite pursuits.

**Submarine Telephonic Communication.**—The German Post Office officials have been experimenting during the last few days with the North Sea cable, 75 kilometres long, between Heligoland and Cuxhaven, to test the possibility of using submarine cables of considerable length for telephonic purposes. The results have been very favourable, distinct communication having been obtained at both ends.

**Personal.**—Mr. Oswald Haes, who is an old student of Finsbury Technical College, and has been on the engineer's staff of the Brush Electrical Engineering Company and its predecessor, the Anglo-American Company, for three years, has been appointed to the management of the engineering department of the company's branch in Australia, and is shortly proceeding to Sydney, N.S.W., to take up his position.

**Electric Lighting for Lewes.**—At a largely-attended meeting of Lewes ratepayers, held on Wednesday night, under the presidency of the Mayor, it was decided by an overwhelming majority to adopt electricity for street lighting.

**Business Extensions.**—Messrs. Paterson and Cooper inform us that they have opened a West-end showroom at 3, Prince's Mansions, Victoria Street, Westminster, where it is proposed to keep samples of manufactures.

**The Eight Hours Bill.**—Mr. R. W. McLeod Fullerton, Unionist candidate for the East Division of Edinburgh, addressing the electors, said he supported the right of the individual to freedom of action and making of contracts; but to the general principle he would make exceptions, such as in cases where there was a temptation both to employers and employed, or to either, to make agreements which were prejudicial to the health and comfort of the workman. He pointed to the case of the telegraph offices in large towns, where seven hours' work a day was as much as the telegraph clerks could stand. He would be in favour of a commission of inquiry as to the amount of work in the various telegraph offices in the country, with the view of determining in what offices a compulsory seven hours day should be fixed.

**Electrolysis versus Paracentesis in Ovarian Cysts.**—Dr. Sigmund Cserey, writing in a Hungarian medical journal, points out the great advantage that electrolysis possesses over paracentesis in ovarian cysts where more radical operative measures are for any cause inadmissible. The enormous loss of albumen by tapping is frequently followed by serious weakening of the patient, which is not the case where electrolysis is employed, this method causing the proteid to be partially re-absorbed by the system. He mentions a case where an ovarian cyst had been tapped twelve years previously, but had very soon filled again. Since then electrolysis had been several times employed with far more lasting results. He used a 20-cell Smee's battery, the anode being a needle, which was inserted into the abdomen to the depth of 3 inches and a half, and the cathode, a large flat surface, applied to the lower part of the back. The circuit was opened with two cells, and gradually raised to 14, which caused so severe a burning pain that the number was reduced. The whole sitting lasted 35 minutes. The good effects were soon seen in the increase of the urine and the decrease of the circumference of the abdomen.

**A Novel Use for the Electric Motor.**—The convenience of the electric motor is being shown to crowds who watch the Sioux City Corn Palace, now in course of construction. About 15,000 bushels of corn are used to decorate the building. Last year the saws to split the corn were run by four horses, and the irregular speed caused much annoyance. This year a 3 H.P. Hawkeye electric motor belted direct to a saw does all the work much more satisfactorily, one man sawing about 60 bushels an hour, to supply over 200 men and about the same number of women, who are decorating the building. For working at night the immense structure is illuminated by 50 arc lights and over 1,000 incandescents.

---

#### NEW COMPANIES REGISTERED.

---

**Henry Leggott & Co. Limited.**—Capital, £20,000 in £10 shares. Objects: To trade as electrical engineers, iron and brass founders, and to take over the business of Henry Leggott and Co., ironmongers, domestic, sanitary and gas engineers. Signatories (with 1 share each):—\*J. R. Cordingley; E. Greaves; J. L. Wilson; \*J. R. Birkinshald and J. J. Colefax, all of Bradford; \*Hy. Leggott, Hepperholme; \*R. Leggott, Harrogate. The signatories denoted by an asterisk are the first directors. Qualification £500 in shares or stock, remuneration £1 ls. each for every meeting attended. Registered 7th inst by R. Jordan, 120, Chancery Lane. Registered office, 73, Market Street, Bradford.

**Cape Town and District Gas Light and Coke Company, Limited.**—Capital, £100,000 in £10 shares. Objects: To purchase the gas works of the Cape Town Gas Light Company, Limited, and to carry on the business of the same. To carry on the Cape Town and its districts, and in South Africa, England and elsewhere, the business of an electric lighting and power company in all branches, including the manufacture, sale, and supply of electricity for light, motive power, and other purposes. Signatories: \*R. A. Fairclough, 14, Bunhill Row; \*J. Boustead, 34, Craven Street; \*H. R. Savory, 11 & 12, Cornhill, 100 shares each; Wm. Lewis, D. Sluter, F. H. Leslie, J. A. Kelman, all of 251, Winchester House, 5 shares each. The first directors are the signatories devoted by an asterisk, and the Hon. Hy. Noel. Qualification, £1,000 in shares. Remuneration, £1,200 per annum divisible. Registered 9th inst. by Paine, Son & Pollock, 14, St. Helen's Place.

### OFFICIAL RETURNS OF ELECTRICAL COMPANIES.

**International Okonite Company, Limited.**—An agreement of 18th July between Woodhouse and Rawson United, Limited (the vendors) and this company, cites that by an agreement of 24th June it was agreed that the vendors should sell to the company the business and properties therein described for £324,990, of which £113,330 was to be payable by the allotment of fully paid preference and ordinary shares, the amount of such shares respectively to be fixed by the vendors, provided that not less than £50,000 of either description be allotted. Under the present agreement the vendors fix the amount to be allotted in preference shares at £61,160, and the amount to be allotted in fully paid ordinary shares at £52,170.

An agreement of 30th July between the same parties provides that the proportion of the purchase money payable in shares shall be £113,320 instead of £113,330, and payable £56,660 in fully paid preference shares and £56,660 in fully paid ordinary shares.

**Mulholland, Maugham and Company, Limited** (mechanical and electrical engineers).—An agreement of 14th August, filed 27th ult., relates to the purchase by the company of the Mulholland, Maughan & Co., of West Carnforth, Durham, the consideration being the allotment of 120 fully paid £10 founders' shares, which will be entitled to one-half the surplus net profits remaining after payment of  $7\frac{1}{2}$  per cent. per annum dividend upon all the shares.

**Northern Counties Electric Light and Power Supply, Limited.**—The registered office of this company is situate at 13, Victoria Street, Westminster.

**Grange Syndicate, Limited** (Groth's Electric Tanning System).—The registered office of this company is situate at 3, Tokenhouse Buildings, Bank, E.C.

**Weston House-to-House Electricity Supply, Limited.**—The registered office of this company is at 13, John Street, Bristol.

**Paddington and Bayswater Electric Light and Power Supply, Limited.**—The registered office of this company is situate at 13, Victoria Street, Westminster.

### CITY NOTES, REPORTS, MEETINGS, &c.

#### Woodhouse and Rawson United, Limited.

At the general meeting of the shareholders, held at Winchester House, on Friday, the 10th, Lord Aberdare presided, and in moving the adoption of the report and accounts, said: There were two points in the former to which he desired to call attention. The first was that the ordinary shares, of which one-half

remained uncalled, were those that were taken by the public; the shares allotted to the vendors, and which of course were fully paid, stood in the balance sheet. As regards the other point, the report mentioned that the Sociedad Española de Electricidad, in Barcelona, had placed the whole of its arrangements for improving and extending the lighting of that city by electricity in the hands of the company. The contract had been made with Woodhouse and Rawson, Limited, and it had been taken over by the present company, and at the present time the Barcelona Society was engaged in carrying out the company's suggestions. A board of directors might present its report in two ways: it might present the report and resolutions in the briefest and most succinct form, leaving it to the Chairman to supply any special facts and explanations which might be called for; or the report might take the form of a detailed account of the company and its development and its prospects for the future. The directors of Woodhouse and Rawson United, Limited, had chosen to take the latter course, which has the further advantage that it relieved the chairman from making a very long speech. Those who had carefully studied the report would see how numerous and important the operations had been. To some they might seem incongruous, but a little reflection would show that in reality there was a close connection between them. The manufacturing, supply and contract departments explained themselves. The development of the business, the taking over and bringing out of new inventions by the purchase of patents or of manufacturing under royalties to inventors formed a large and lucrative portion of the business, as also did that portion of the business which consisted in aiding in the formation of companies which require capital beyond their means, and experience which they did not possess. All these branches of electrical business were undertaken by the several companies purchased by and absorbed into this company. They had in their various departments been extended as rapidly as the short period of the company's existence permitted. The manufacturing, supply and contract departments had made considerable improvement in actual performance, and gave what the speaker ventured to call a well-grounded promise of further extension. Altogether the report presented a picture of great activity which, with time and opportunity, could be greatly extended. In his opinion to the three branches, manufacture, supply and contract, was due the solid basis upon which the ultimate success of the company should rest. Obviously expectations of large profits from those sources could only be gradually realised. They must sow before they could reap. It would be unusual and, he thought, inadvisable to enter minutely into the source of profits in the case of a manufacturing company like this. But this much he might say: the large profits of the present year had enabled the directors to recommend a dividend of 15 per cent. per annum without availing themselves of the £75,000 deposited by Woodhouse and Rawson, Limited, to guarantee that amount of dividend for three years, had enabled the directors to place £25,000 to the reserve fund, to carry forward over £16,000 to next year's accounts, and to write off £7,421 against the estimated value of the patents. These large profits had been mainly derived from the fourth branch of the company's business, viz., the testing and approving of new patents and inventions connected with electrical and engineering science, and their introduction to the public either by making arrangements for working them, or by assisting the owners and inventors in forming separate companies for that purpose. Such were the operations of Woodhouse and Rawson, Limited, in introducing the Elmore process, which the present company was, with every prospect of success, extending over the chief commercial centres of Europe; the International Okonite Company, the West Kensington Co-operation Stores, &c. That there was a certain risk involved in the introduction of new inventions it would be absurd to deny, but he could honestly say that the operations referred to had never been undertaken without the most careful enquiry that the judgment, experience and knowledge of firms possessed by the board had been able to exercise. They represented, in fact, a very small proportion of the proposals made for the board's assistance in one form or another, the vast majority of which had been rejected, because the board limited itself to the selection of such as seemed thoroughly sound and of intrinsic value. It was a mere act of justice to the managing director, Mr. F. L. Rawson, to say that the success hitherto attained had been mainly owing to his initiative, and the extreme energy and ability he had displayed. Neither could the speaker refrain from expressing his personal sense of gratitude to their vice-chairman, Sir Rawson W. Rawson, for his great exertions and the unlimited attention to the affairs of the company, especially during the period of severe illness which he, the speaker, had undergone. To his other colleagues, also, he tendered his grateful acknowledgments. The report spoke in by no means exaggerated terms of the unusual demands which had been made upon the time of the staff, owing to the pressure involved in a new company engaged in such extensive operations, and the speaker begged to add his own acknowledgments of the way in which the staff had performed its duties, and to warmly recommend the adoption of the resolution for the formation of an employe's pension fund. Might he be permitted to make some suggestions which were the fruit of past years' experience. First, he thought it very desirable that the company's capital should be increased, and he trusted that the board would ere long submit resolutions with that object. The report told them that the directors had already considerably extended the business and the business premises of the company, but he must tell them that these extensions could not be fully developed nor made as profitable as they might without an addition to the working capital. At present

they had the use of the £75,000 deposited with them by Woodhouse and Rawson, Limited, but that would have to be repaid two years hence at the latest. It might be worth while to do so earlier, if satisfactory arrangements could be made with the liquidators, to whom doubtless it would be of great advantage also. That was a matter for the future; still he thought it advisable to prepare the shareholders for possible proposals in that direction. His other suggestions related to an increase in the numbers of the board and working staff. He had already referred to the heavy responsibilities which had rested upon the board, which consisted, he might say, of seven only during the past year, in the conduct of the company's general business, and in sifting the various schemes brought before them, and he need not enlarge further upon that point. Such a business could not be properly carried on without great expenditure of time and labour, and long and frequent discussion. He saw little probability of a diminution of the directors' work in the near future, and he did not think that the present pressure upon them could long be continued, or that it ought to be. He would, therefore, venture to suggest the increase of the board to nine, the full number authorised by the articles of association, and that the directors' remuneration also should be increased by the allowance of a percentage on the net profits of the year. The present remuneration was inadequate to gentlemen who are obliged to give so large a part of their time to the superintendence of this great and growing business. As regards the working staff, with the best will in the world the board of directors could be little more than a consultative body; the initiative, no less than the details of the company's operations, must rest with the executive staff. Theirs was an excellent one so far as it went, but no man ought to be called upon to do all the work which at present fell upon many of the company's officers, and more especially upon the managing director. There ought to be some further division of labour, the cost of which would be inconsiderable as compared with the increased efficiency in the external and internal management. It only remained to thank the meeting for the patience with which they had listened to his remarks, to echo the congratulations of the report upon the company's achievements in the past year, and its present position and prospects, and to express the earnest hope that the shareholders would with a unanimous vote support the board in its efforts to give stability to an enterprise which had begun so well. He trusted the reasons given in the report for his resignation would be thought sufficient, and he congratulated the shareholders on the new director proposed for their acceptance. The high character of Sir Edward Thornton for ability and honour in his past career as a foreign minister was well known, and he hoped they would re-elect Sir Rawson Rawson as a director. It was the board's intention to request Sir Rawson Rawson to assume the chairmanship, and he need not say that he entirely concurred in the choice made. In conclusion, he was happy to announce that the affairs of the Woodhouse and Rawson Company, Limited, might now be considered as settled, after long and vexatious endeavours to bring that settlement to an earlier conclusion, and he was happy to hear that the shares were already on their way to the various long-expectant shareholders.

Sir Rawson Rawson seconded the motion. He said invention in the present day in connection with electricity was advancing so rapidly, that it only required energy and prudence on the company's part to ensure numerous offers of most valuable inventions. They had now in course of examination and testing some exceedingly valuable patents.

A Shareholder noticed in the balance sheet that the number of ordinary and of fully paid shares issued amounted to 34,633, whereas on January 29th the company issued a statement to the effect that 36,316 had been issued. He would like to know, also, whether £31,000 was not an unusual amount of cash to keep in hand.

Mr. F. L. Rawson, with regard to the first question, said the shareholders might be assured that whatever statements had been made they were absolutely correct. As regards the other point, the explanation was that a cheque for £30,000 had not yet been paid into the bank when the balance sheet was made up, but was paid immediately afterwards.

Another Shareholder pointed out that that some of the vendors' shares had not yet been allotted.

The Chairman said they had now been allotted. The delay was owing to the directors having had to wait for the liquidator's instructions of Woodhouse and Rawson, Limited.

Another Shareholder asked what proportion of the £91,000 and odd put down as profit was *bona fide* trade earnings?

The Chairman declined to enter into questions of that kind. It was not, he considered, in the interests of the company to give these explanations, although the questions occurred very naturally to the shareholders.

Mr. F. L. Rawson, replying to another shareholder, said that he expected that the Stock Exchange would grant the company a quotation in about a week's time.

The resolution was agreed to.

The Chairman then moved to declare dividends at the rate of  $7\frac{1}{2}$  per cent. and 4 per cent. on the preference shares, making, with the interim dividend of  $7\frac{1}{2}$  per cent. already paid upon the ordinary shares, and 4 per cent. already paid upon the preference shares a dividend of 15 per cent. per annum on the ordinary and of 8 per cent. per annum on the preference shares. He observed that the 7 per cent. preference shares were entitled to an extra 1 per cent. each year that the ordinary shareholders received 10 per cent. per annum.

Sir Rawson W. Rawson was re-elected a director, and Sir

Edward Thornton was elected a director in the place of Lord Aberdare. Messrs. Pixley & Co. were reappointed auditors at a remuneration of 100 guineas.

A resolution to increase the directors remuneration from 30th June, 1890, by a commission of 2 per cent. on the net profits of the company was agreed to unanimously.

Mr. Pope, Q.C., one of the directors, in the course of a few remarks said it might interest some shareholders to know that Mr. Philip Rawson, one of the directors, was in no way related to Sir Rawson Rawson. As representing the general body of the shareholders he, Mr. Pope, would jealously watch anything like a family party administration in a concern of this magnitude, and from his continuing to hold his place on the board, the shareholders might be satisfied that no such disposition had been manifested. After praising Sir Rawson Rawson's self-sacrifice and attention to the company's affairs, and expressing regret at Lord Aberdare's retirement, he went on to say that, of course, no one would imagine that £91,000 a year profit was one that could be made by the manufacture and supply of electrical apparatus. As one connected with other electrical companies, he knew pretty nearly the scale of profit to be made in such businesses. It would not be desirable to disclose to competitors the exact amount of profits the company made. It they were very large, it would provoke competition; if small, it would disclose an unfortunate state of affairs. The shareholders might be well content with what had been placed to their credit, without being very anxious to enquire into the particular source of profit. But he strongly advised them to see at all times that the profits were real. They must be well content that they were receiving 15 per cent. upon money which had only been invested for about twelve months. He advocated the maintenance of a strong reserve against contingencies. A business like this was, after all, not so steady as an ordinary trading concern; it must be more or less speculative. Since the balance sheet was made the company's profits had not fallen off. To Mr. F. L. Rawson was due the remarkable energy, and to Lord Aberdare and Sir Rawson Rawson the prudence with which the companies affairs had been conducted.

Mr. F. Rawson spoke of the *employés* pension fund as an inducement to *employés* to remain in the company's service, and said that probably the shareholders would be asked at a general meeting to sanction the scheme. With a vote of thanks to the board, and to Lord Aberdare in particular, the proceedings terminated.

### The Brazilian Submarine Telegraph Company, Limited.

THE report of the directors and the accounts for the half-year ended 30th June, 1890, to be submitted to the 34th ordinary general meeting, 22nd October, 1890, states that:—

The directors submit the annexed accounts and balance-sheet for the half-year ended 30th June, 1890.

The revenue for this period amounted to £121,873 19s. 9d., and the working expenses to £16,492 5s. 3d. After providing £12,880 for debenture interest and sinking funds, and £1,559 17s. 1d. for income tax, there remains a balance of £90,941 17s. 5d.; to this is added £9,975 0s. 8d. brought forward from 31st December last, making a total of £100,916 18s. 1d. A quarterly interim dividend amounting to £19,500 has been paid, and £40,000 transferred to the reserve fund, increasing that fund to £352,626 2s. 11d.

The directors now recommend the declaration of a final dividend of 3s. per share, making with the interim dividends, a total dividend of 6 per cent. for the year, and also the payment of a bonus of 3s. per share, both free of income tax, which together will amount to £39,000, being a distribution in the aggregate of  $7\frac{1}{2}$  per cent. for the year ended 30th June, 1890, leaving a balance of £2,416 18s. 1d. to be carried forward. The dividend and bonus will be payable on the 23rd instant.

On the 31st July last the sum of £15,300 was transferred to pay off the 153 bonds of the 1884 issue, drawn for redemption in April last. This repayment reduces the debenture debt to £144,200.

The receipts for the half-year include the sum of £1,500 dividend to 31st December, 1889, on the company's shares in the African Direct Telegraph Company, Limited.

The various sections of the company's line are in good working order.

Sir James Anderson and Mr. Frederick Youle retire by rotation at this meeting, and being eligible for re-election as directors offer themselves accordingly.

The two auditors, Mr. Henry Dever and Mr. John Gane, also offer themselves for re-election.

### The Direct United States Cable Company, Limited.—

The board has resolved upon the payment of an interim dividend at the rate of  $3\frac{1}{4}$  per cent. per annum, for the quarter ending 30th September, 1890.

### TRAFFIC RECEIPTS.

The Western and Brazilian Telegraph Company, Limited. The receipts for the week ending October 10th, after deducting the fifth of the gross receipts payable to the London Platino-Brazilian Telegraph Company, Limited, were £4,21.

## SHARE LIST OF ELECTRICAL COMPANIES.

THE ELECTRO-MAGNET.\*

By Prof. SILVANUS P. THOMPSON, D.Sc., B.A., M.I.E.E.

(Continued from page 439.)

Now the law of traction being in that way established, one at once begins to get some light upon the subject of the design of electro-magnets. Indeed, without going into any mathematics, Joule had foreseen this when he in some instinctive sort of way seemed to consider that the proper way to regard an electro-magnet for the purpose of traction was to think how many square inches of contact surface it had. He found that he could magnetise iron up until it pulled with a force of 175 lbs. to the square inch, and he doubted whether a traction as great as 200 lbs. per square inch could be obtained.

In the following table Joule's results (see Table I.) are recalculated, and the values of B deduced:—

TABLE VII.—Joule's RESULTS RE-CALCULATED.

Description of electro-magnet.		Section.		Load.		Lbs. per sq. in.	Kilos. per sq. cm.	B	Ratio of load to weight.
		sq. in.	sq. cm.	lbs.	kilos.

I will now return to the data on Table VI., and will ask you to compare the last column with the first. Here are the various values of B, that is to say, the amounts of magnetisation you get into the iron. You cannot conveniently crowd more than 20,000 magnetic lines to the square centimetre of the best iron, and, as a reference to the curves of magnetisation shows, it is not expedient in the practical design of electro-magnets to attempt, except in extraordinary cases, to crowd more than about 16,000 magnetic lines into the square centimetre. The simple reason is this, that if you are working up the magnetic force, say from 0 up to 50, a magnetising force of 50 applied to good wrought iron, will give you only 16,000 lines to the square centimetre, and the permeability by that time has fallen to about 320. If you try to force the magnetisation any further, you find that you have to pay for it so greatly. If you want to force another 1,000 lines through the square centimetre, to go from 16,000 to 17,000, you have to add on an enormous magnetising force; you have to double the whole force from that point to get another 1,000 lines added. Obviously it would be much better to take a larger piece of iron and not to magnetise it too highly—to take a piece a quarter as large again, and to magnetise that less forcibly. It does not therefore pay to go much above 16,000 lines to a square centimetre—that is to say, expressing it in terms of the law of traction, and the lbs. per square inch, it does not pay to design your electro-magnet so that it shall have to carry more than about 150 lbs. to the square inch. This shall be our practical rule: let us at once take an example. If you want to design an electro-magnet to carry a load of one ton, divide the ton, or 2,240 lbs., by 150, and that gives the requisite number of square inches of wrought iron, namely, 14.92, or say 15. Of course, one would work with a horse-shoe shaped magnet, or something equivalent—something with a return circuit—and calculate out the requisite cross-section, so that the total area exposed might be sufficient to carry the given load at 150 lbs. to the square inch. And, as a horse-shoe magnet has two poles, the cross-section of the bar of which it is made must be  $7\frac{1}{2}$  square inches. If of round iron, it must be about  $3\frac{1}{4}$  inches in diameter; if of square iron, it must be  $2\frac{1}{2}$  inch each way.

That settles the size of the iron, but not the length. Now the length of the iron, if one only considers the law of the magnetic circuit, ought to be as short as it can possibly be made. Reflect for what purpose we are designing. The design of an electro-magnet is to be considered, as every design ought to be, with a view to the ultimate purpose to be served by that which you are designing. The present purpose is the actual sticking on of the magnet to a heavy weight, not acting on another magnet at a distance, not pulling at an armature separated from it by a thick layer of air; we are dealing with traction in contact. The question is—how long a piece of iron shall we need to bend over? The answer is—take length enough, and no more than enough, to permit of room for winding on the necessary quantity of wire to carry the current which will give the requisite magnetising power. But this latter we do not yet know; it has to be calculated out by the law of the magnetic circuit. That is to say, we must calculate the magnetic flux, and the magnetic reluctance as best we can; then from these calculate the ampère-turns of current; and from this calculate the needful quantity of copper wire, so arriving finally at the proper length of the iron core. It is obvious the

cross-section being given, and the value of B, being prescribed, that settles the whole number of magnetic lines, N, that will go through the section. It is self-evident that length adds to the magnetic reluctance, and, therefore, the longer the length is, the greater have to be the number of ampère-turns of circulation of the current; while the less the length is, the smaller need be the number of ampère-turns of circulation. Therefore you should design the electro-magnet as stumpy as possible, that is to say, make it a stumpy arch, even as Joule did when he came across the same problem, and arrived, by a sort of scientific instinct, at the right solution. You should have no greater length of iron than is necessary in order to get the windings on. Then you see we cannot absolutely calculate the length of the iron until we have an idea about the winding, and we must settle, therefore, provisionally, about the windings. Take a simple ideal case. Suppose we had an indefinitely long, straight iron rod, and we wound that from end to end with a magnetising coil. How thick a coil, how many ampère-turns of circulation per inch length, will you require in order to magnetise up to any particular degree? It is

a matter of very simple calculation. You can calculate exactly what the magnetic reluctance of an inch length of the core will be. For example, if you are going to magnetise up to 16,000 lines per square centimetre, the permeability will be 320. You can take the area anything you like, and consider the length of one inch; you can therefore calculate the magnetic reluctance per inch of conductor, and then you can at once say how many ampère-turns per inch would be necessary in order to give the desired indication of 16,000 magnetic lines to the square centimetre. And knowing the properties of copper wire, and how it heats up when there is a current; and knowing also how much heat you can get rid of per square inch of surface, it is a very simple matter to calculate what minimum thickness of copper the fire insurance companies would allow you to use. They would not allow you to have too thin a copper wire, because if you provide an insufficient thickness of copper, you still must drive your ampères through it to get a sufficient number of ampère-turns per inch of length; and if you drive those ampères through copper winding of an insufficient thickness the copper wire will over-heat, and your insurance policy will be revoked. You therefore are compelled, by the practical consideration of not over-heating, to provide a certain thickness of copper wire winding. I have made a rough calculation for certain cases, and I find that for such electro-magnets as one may ordinarily deal with, it is not necessary in any case of practical work to use a copper wire winding, the total thickness of which is greater than about half-an-inch; and, as a matter of fact, if you use as much thickness as half-an-inch, you need not then wind the coil all along, for if you will use copper wire winding, no matter what the size, whether thin or thick, so that the

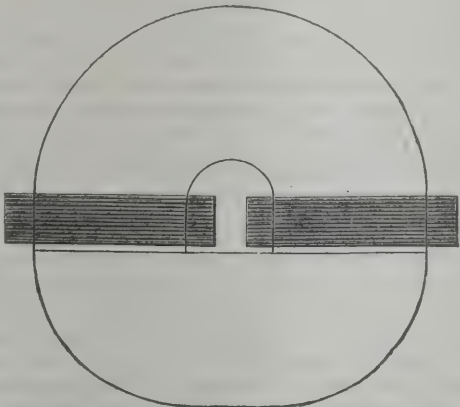

FIG. 23.—STUMPY ELECTRO-MAGNET.

total thickness of copper outside the iron is half-an-inch, you can without over-heating, using good wrought iron, make one inch of winding do for 20 inches length of iron. That is to say, you do not really want more than  $\frac{1}{20}$ th of an inch of thickness of copper outside the iron to magnetise up to the prescribed degree of saturation that indefinitely long piece of which we are thinking, without over-heating the outside surface in such a way as to violate the insurance rules. Take it roughly, if you wind to a

\* Cantor Lecture. Delivered before the Society of Arts, January 27th, 1890.

thickness of half-an-inch, the inch length of copper will magnetise 20 inches length of iron up to the point where  $B$  equals 16,000. If then we have a bar bent into a sort of horse-shoe in order to make it stick on to a perfectly-fitting armature also of equal section and quality, we really do not want more than one inch along the inner curve for every 20 inches of iron. An extremely stumpy magnet, such as I have sketched in Fig. 23, will therefore do if one can only get the iron sufficiently homogeneous throughout. If instead of crowding the wire near the polar parts, we could wind entirely all round the curved part, though the layer of copper winding would be half-an-inch thick inside the arch, it would be much less outside. Such a magnet, provided the armature fitted with perfect accuracy to the polar surfaces, and provided a battery were arranged to send the requisite number of ampères of current through the coils, would pull with a force of one ton, the iron being but  $3\frac{1}{2}$  inches in diameter. For my own part, in this case I should prefer not to use round iron, one of square or rectangular section being more convenient; but the round iron would take less copper in winding, as each turn would be of minimum length if the section were circular.

Now, this sort of calculation requires to be greatly modified directly one begins to deal with any other case. A stumpy short magnetic circuit with great cross-section is clearly the right thing for the greatest traction. You will get the given magnetisation and traction with the least amount of magnetising force when you have the area as great as possible, and the length as small as possible. You will kindly note that I have given you as yet no proofs for the practical rules that I have been using: they must come later. Also I have said nothing about the size of the wire, whether thick or thin. That does not in the least matter; for the ampère-turns of magnetising power can be made up in any desired way. Suppose we want on any magnet one hundred ampère-turns of magnetising power, and we choose to employ a thin wire that will only carry half an ampère, then we must wind 200 turns of that thin wire. Or, suppose we choose to wind it with a thick wire that will carry ten ampères, then we shall want only ten turns of that wire. The same weight of copper, heated up by the corresponding current to an equal degree of temperature, will have equal magnetising power when wound on the same core. But the rules about winding the copper will be considered later.

Now, if you look in the text-books that have been written on magnetism for information about the so-called lifting power or portative force of magnets—in other words, the traction—you will find that from the time of Bernoulli downwards, the law of portative force has claimed the attention of experimenters, who, one after another have tried to give the law of portative force in terms of the weight of the magnets; usually dealing with permanent magnets, not electro-magnets. Bernoulli gave\* a rule something of the following kind, which is commonly known as Häcker's rule—

$$P = a \sqrt[3]{W};$$

where  $w$  is the weight of the magnet,  $P$ , the greatest load it will sustain, and  $a$  a constant depending on the units of weight chosen, on the quality of the steel, and on its goodness of magnetisation. If the weights are in pounds then  $a$  is found, for the best steels, to vary from 18 to 24 in magnets of horse-shoe shape. This expression is equivalent to saying that the power which a magnet can exert—he was dealing with steel magnets; there were no electro-magnets in Bernoulli's time—is equal to some constant multiplied by the three-halft root of the weight of the magnet itself. The rule is accurate only if you are dealing with a number of magnets all of the same geometrical form, all horse-shoes let us say, of the same general shape, made from the same sort of steel, similarly magnetised. In former years I pondered much on Häcker's rule, wondering how on earth the three-halft root of the weight could have anything to do with the magnetic pull; and having cudgelled my brains for a considerable time, I saw that there was really a very simple meaning in it. What I arrived at was this. If you are dealing with a given material, say hard steel, the weight is proportional to the volume, and the cube root of the volume is something proportional to the length, and the square of the cube root forms something proportional to the square of the length, that is to say, to something of the nature of a surface. What surface? Of course the polar surface. This complex rule, when thus analysed, turns out to be merely a mathematician's expression of the fact that the pull for a given material magnetised in a given way is proportional to the area of the polar surface; a law which in its simple form Joule seems to have arrived at naturally, and which in this extraordinarily academic form was arrived at by comparing the weights of magnets with the weight which they would lift. You will find it stated in many books that a good magnet will lift 20 times its own weight. There never was a more fallacious rule written. It is perfectly true that a good steel horse-shoe magnet weighing 1 lb. ought to be able to pull with a pull of 20 lbs. on a properly-shaped armature. But it does not follow that a magnet which weighs 2 lbs. will be able to pull with a force of 40 lbs. It ought not to, because a magnet that weighs 2 lbs. has not poles twice as big if it is the same shape. In order to have poles twice as big you must remember that three-halft root coming in. If you take a magnet that weighs eight times as much, it will have twice the linear dimensions and four times the

surface; and with four times the surface in a magnet of the same form, similarly magnetised, you will have four times the pull. With a magnet eight times as heavy you will have only four times the pull. The pull, when other things are equal, goes by surface, and not by weight, and therefore it is ridiculous to give a rule saying how many times its own weight a magnet will pull. It is also narrated as a very extraordinary thing that Sir Isaac Newton had a magnet, a loadstone, which he wore in a signet ring, which would lift 234 times its own weight. I have had an electro-magnet which would lift 2,500 times its own weight, but then it was a very small one, and did not weigh more than a grain and a-half. When you come to small things, of course the surface is large proportionally to the weight; the smaller you go, the larger becomes that disproportion. This all shows that the old law of traction in that form was practically valueless, and did not guide you to anything at all, whereas the law of traction as stated by Maxwell, and explained further by the law of the magnetic circuit, proves a most useful rule.

From this digression let us return to the law of the magnetic circuit. I gave you in my first lecture, when speaking of permeability, the following rule for calculating the magnetic induction,  $B$ :—Take the pull in lbs., and the area of cross-section in square inches, divide one by the other, and take the square root of the quotient; then multiplying by 1,317 gives  $B$ ; or multiplying by 8,494 gives  $B_{\mu}$ . We have therefore a means of stepping from the pull per square inch to  $B_{\mu}$ , or from  $B_{\mu}$  to the pull per square inch. Now the other rule of the magnetic circuit also enables us to get from the ampère-turns down to  $B_{\mu}$ , for previously we have the following expression for the ampère-turns:—

$$si = N \times \Sigma \frac{l''}{A''\mu} \times 0.3132,$$

and  $N$ , the whole number of magnetic lines in the magnetic circuit is equal to  $B_{\mu}$  multiplied by  $A''$ , or

$$N = B_{\mu} A''.$$

From these we can deduce a simple direct expression, provided we assume the quality of iron as before, and also assume that there is no magnetic leakage, and that the area of cross-section is the same all round the circuit, in the armature as well as in the magnet core. So that  $l''$  is simply the mean total path of the magnetic lines all round the closed magnetic circuit. We may then write

$$si = \frac{B_{\mu} l''}{\mu} \times 0.3132;$$

whence

$$B_{\mu} = \frac{\mu \times si}{l'' \times 0.3132}.$$

But by the law of traction, as stated above,

$$B_{\mu} = 8,494 \sqrt{\frac{P \text{ (lbs.)}}{A \text{ (sq. in.)}}}$$

Equating together these two values of  $B_{\mu}$ , and solving, we get for the requisite number of ampère-turns of circulation of exciting currents:—

$$si = 2,661 + \frac{l''}{\mu} \times \sqrt{\frac{P \text{ (lbs.)}}{A \text{ (sq. in.)}}}$$

This, put into words, amounts to the following rule for calculating the amount of exciting power that is required for an electro-magnet pulling at its armature, in the case where there is a closed magnetic circuit with no leakage of magnetic lines. Take the square root of the pounds per square inch; multiply this by the mean total length (in inches) all round the iron circuit; divide by the permeability (which must be calculated from the pounds per square inch by help of Table VI. and Table II.); and finally multiply by 2,661: the number so obtained will be the number of ampère-turns. One goes at once from the pull per square inch to the number of ampère-turns required to produce that pull in a magnet of given length, and of the prescribed quality. In the case where the pull is specified in kilogrammes, the area of section in square centimetres, and the length in centimetres, the formula becomes

$$si = 3,951. \frac{l}{\mu} \sqrt{\frac{P}{A}}.$$

As an example, take a magnet core of round annealed wrought iron, half-an-inch in diameter, 8 inches long, bent to horse-shoe shape. As an armature, another piece, 4 inches long, bent to meet the former. Let us agree to magnetise the iron up to the pitch of pulling with 112 lbs. to the square inch. Reference to Table VI. shows that  $B_{\mu}$  will be about 90,000, and Table II. shows that in that case  $\mu$  will be about 907. From these data calculate what load the magnet will carry, and how many ampère-turns of circulation of current will be needed.

Ans.—Load (on two poles) = 43.97 lbs.  
Ampère-turns needed = 372.5

N.B.—In this calculation it is assumed that the contact surface between armature and magnet is perfect. It never is; the joint offers additional resistance to the magnetic lines, and there will be some leakage. It will be shown later how to estimate these effects, and to allow for them in the calculations.

Here let me go to a matter which has been one of the paradoxes of the past. In spite of Joule, and of the laws of traction, showing that the pull is proportional to the area, you have this anomaly—that if you take a bar-magnet having flat ended poles, and measure the pull which its pole can exert on a perfectly flat armature, and

\* *Acta Helvetica* III., p. 233, 1758.

† *Philosophical Magazine*, July, 1888.

then deliberately spoil the truth of the contact surface, rounding it off, so making the surface gently convex, the convex pole, which only touches at a portion of its area instead of over the whole, will be found to exert a bigger pull than the perfectly flat one. It has been shown by various experimenters, particularly by Nicklès, that if you want to increase the pull of a magnet with armatures, you may reduce the polar surface. Old steel magnets were frequently purposely made with a rounded contact surface. There are plenty of examples. Suppose you take a straight round core, or one leg of a horse-shoe which answers equally, and take a flat-ended rod of iron of same diameter as an armature; stick it on endwise, and measure the pull when a given amount of ampère-turns of current is circulating round. Then having measured the pull, remove it and file it a little, so as to reduce it at the edges, or actually take a slightly narrower piece of iron, so that it will actually be exerting its power over a smaller area, you will get a greater pull. What is the explanation of this extraordinary fact? A fact it is, and I will show it to you. Here, Fig. 24, is a small

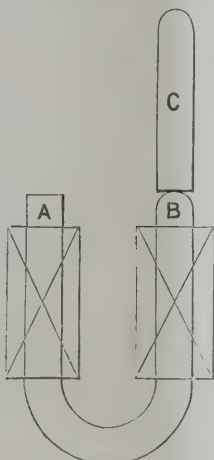

FIG. 24.—EXPERIMENT ON ROUNDING ENDS.

electro-magnet which we can place with its poles upwards. This was very carefully made, the iron poles very nicely faced, and on coming to try them it was found they were nearly equal, but one pole, A, was a little stronger than the other. We have, therefore, rounded the other pole, B, a little, and here I will take a piece of iron, C, which has itself been slightly rounded at one end, though it is flat at the other. I now turn on the current to the electro-magnet, and I take a spring-balance, so that we can measure the pull at either of the two poles. When I put the flat end of C to the flat pole A, so that there is an excellent contact, I find the pull about 2½ lbs. Now try the round end of C on the flat pole, A; the pull is about 3 lbs. The flat end of C on the round pole B is also about 3 lbs. But if now I put together two surfaces that are both rounded, I get almost exactly the same pull as at first with the two flat surfaces. I have made many experiments on this, and so have others. Take the following case:—There is hung up a horse-shoe magnet, one pole being slightly convex and the other absolutely flattened, and there is put at the bottom, on a square bar armature, over which is slipped a hook to which weights can be hung. Which end of the armature do you think will be detached first?

If you were going simply by the square inches, you would say this square end will stick on tighter; it has more gripping surface. But, as a matter of fact, the other sticks tighter. Why? We are dealing here with a magnetic circuit. There is a certain total magnetic reluctance all round it, and the whole number of magnetic lines generated in the circuit depends on two things—on the magnetising force, and on the reluctance all round; and, saving a little leakage, it is the same number of magnetic lines which come through at B as go through at A. But here, owing to the fact that there is at B a better contact at the middle than at the edges of the pole, the lines are crowded into a smaller space, and therefore at that particular place  $B_{\text{middle}}$ , the number of lines per square inch runs up higher, and when you square the larger number, its square becomes still larger in proportion. In comparing the square of smaller  $B_{\text{middle}}$  with the square of greater  $B_{\text{edge}}$ , the square of the smaller  $B_{\text{middle}}$  over the larger area turns out to be less than the square of the larger  $B_{\text{edge}}$ , integrated over the smaller area. It is the law of the square coming in.

As an example, take the case of a magnet pole formed on the end of a piece of round iron 1.15 inch in diameter. The flat pole will have 1.05 inches area. Suppose the magnetising forces are such as to make  $B_{\text{middle}} = 90,300$ , then, by Table VI., the whole pull will be 118.75 lbs., and the actual number of lines through the contact surface will be  $N = 948,150$ . Now suppose the pole be reduced by rounding off the edge till the effective contact area is reduced to 0.9 square inches. If all these lines were crowded through that area, that would give a rate of 105,630 per square inch. Suppose, however, that the additional reluctance and the leakage reduced the number by 2 per cent., there would still be 103,500 per square inch. Reference to Table VI. shows that this gives a pull of 147.7 lbs. per square inch, which multiplied by the reduced area 0.9 gives a total pull of 132.9 lbs., which is larger than the original pull.

(To be continued.)

## SOME GENERAL REMARKS ON TELEPHONE EXCHANGE CONSTRUCTION AND EQUIPMENT.\*

By F. A. PICKERNELL.

THE modern telephone exchange building should be thoroughly fire-proof. False floors and concealed masses of wires should be avoided, for a fire once started in such places is extinguished with great difficulty. In its erection, everything should be sacrificed that in any way interferes with the particular object for which it is built. In the basement racks are to be provided for underground cables. Between the basement and the terminal room a cable shaft or system of ducts is to be constructed. On the top floor are to be located the operating, terminal, battery and power, cloak and lunch rooms. These rooms should be provided with chemical fire extinguishers, and the manager, fire chief, and his assistants thoroughly instructed in their use.

In case of fire every effort should be made to suppress it without calling on the fire department. If the fire should attain considerable proportions, it could at its worst only consume all the combustible matter in the room, for inasmuch as the operating room is on the top floor, the fire could not cripple any of the supporting columns or beams of the building and cause it to fall. If a small fire was started and the average fireman admitted, he would do more damage with his axe and hose than the fire would in entirely consuming the apparatus.

Before a telephone company is in a position to erect a suitable building it is necessary to make definite estimates of the probable extent of the underground work, the ultimate number of subscribers it will be desired to handle at the proposed exchange, the probable number of trunks to other exchanges, the probable number of extra territorial lines, the amount of private wire business, the probable average number of calls per subscriber per day, when the switchboard attains its ultimate capacity. A careful estimate of this kind determines the ultimate capacity of the switchboards, underground cable runs, &c., and consequently fixes the minimum size of the building.

In order that the building may fulfil the requirements of a modern telephone exchange, a technical expert should be provided with these estimates, and his opinion taken before any land is purchased or building erected. He should collaborate with the architect in making the building plans. Mistakes have already been made by telephone companies in adopting plans of good office buildings, and afterwards placing the switchboard wherever room could be found. Such buildings have been found unsuitable for modern telephone exchanges. It does not follow from this that the requirements of a good telephone building are necessarily incompatible with the demands of an office building.

One of the first matters to be considered in planning the building is the handling of the underground cables. The system for bringing in the cables should be thoroughly flexible, and permit of the drawing in and out of any particular cable when the point of ultimate equipment is reached. The cables are to be extended through the basement to vertical rows of ducts, or to a suitable cable shaft, extending to the cable terminal room. The massing of the cables in rows of ducts extending to a large number should be avoided. Wherever it is necessary to pass from one system of ducts to another system, the cable should be brought into a vertical row, thus rendering each cable accessible. Before any building plan is adopted, a complete working plan for the handling of the underground cables should be made. This working plan should show the exact location of every cable in the subway at each turn and the location of its inside terminal.

It is preferable to head up cables in a terminal containing a sneak current and lightning arrester. The sneak current arrester should operate with the current of three-tenths of an ampere in 40 seconds, and the lightning arrester should operate when the potential of the wire rises to 300 volts. By using a combined cable head and strong current arrester, economy and space as well as inexpensiveness are insured. The strong current arrester should be so designed that the lines can be tested at this point, by using suitable plugs. The terminal room should also contain a distributing board and chief inspector's desk. The most economical, compact and flexible distributing board that has yet been devised is that known as the "Hibbard iron distributing board." The cable terminals should be connected with the line side of the distributing board by flexible cable, all connections being solid. The switchboard cables terminate on its other side. For cross connecting wires, okonite wire No. 20 B. and S. gauge, insulated to  $\frac{3}{32}$  of an inch, twisted in pairs, should be used, all connections being solid.

The chief inspector's desk should be located immediately in front of the distributing board and should be provided with a telephone outfit, Morse key and relay, Wheatstone bridge and galvanometer and loops extending to the tower and battery room, local switchboard and chief operator's desk. It should be provided with testing plugs for use at the strong current arrester.

Near the terminal room should be located a power and battery room, and in this room battery racks should be provided upon which operators' transmitter batteries and chief inspector's testing batteries can be located. The battery rack should be wired with waterproof wire in a permanent manner. In this room a gene-

\* Read at the National Telephone Exchange Association, Detroit, September, 1890.

rator switchboard should be provided, and have terminating upon it loops to the various portions of the multiple board and also the terminals of all generators. Electric motors, water motors, or other suitable power supply, should be located here. Both the terminal room and battery and power room should be so located that it will be possible to enter them without passing through the operating room.

On the same floor and adjacent to the terminal room should be located the operating room. This room should be large and well ventilated, free from elevator shafts, columns or other obstructions. The switchboard should commence at the end of the operating room nearest the terminal room, and extend from it in a straight line. If it becomes necessary to deflect the switchboard from a straight line, it should be arranged so that the operators sit on the inside of the curve. This enables the chief operator's desk to be so located that all parts of the switchboard are visible from this point. The size of the room necessary will depend upon the ultimate capacity of the switchboard.

If the switchboard is to have an ultimate capacity of 4,000 lines or over the extra territorial trunk section should be the first in the system. It should be equipped with five-point spring jacks and three-point plugs, so that when a line is in use at the trunk section it tests busy at the other boards.

If a switchboard is to have a capacity of less than 4,000 lines, the trunk-board should be made the last section in the system, and the regular Chicago spring jack used. The reason for locating it last in the system is as follows:—Whenever a metallic circuit connection is made at any section, an open leg is attached, which extends throughout the rest of the board, to the answering jack, the open leg being shortest on connections made at the last section. In large boards, this introduces an appreciable amount of cross-talk. By making the trunk line section the last section in the board, all connections made at this board have a minimum length of open leg, and consequently the switchboard cross-talk is reduced to a minimum. The answering jack should be the last spring jack in the system, thus ensuring in every connection at least one of the parties connected having no open leg attached to his circuit. If the answering jack were the first spring jack in the section, every connection would have at least one open leg attached to it extending throughout the whole system.

Next to the trunk section comes the regular multiple board, the number of sections depending upon its present equipment. It has been found that the sections of multiple board six panels wide, of the hog-trough type, and having an ultimate capacity of 300 subscribers' drops, is the most desirable form of multiple switchboard. On the back of the hog-trough is to be located tubular clearing-out drops and tubular subscribers' drops. Immediately back of the hog-trough is to be located a cord shelf upon which both cords are to be placed. In the face of the board, immediately above the cord shelf, is to be placed the answering jacks; above the answering jacks, the subscribers' jacks.

The standard condenser listening and long-distance ringing keys with talking contacts of platinum have been found to give most excellent service. On the framework immediately under and back of the cord shelf is to be located an intermediate distributing board. It has been found that it is possible to so distribute the busy subscribers with those that are not so busy, as to make approximately equal the work for all the operators. In order to do this, without changing the number of the subscriber, the intermediate distributing board has been designed. One side of this board is connected to the answering jack and subscribers' drop, and the other side to the cables coming from the multiple board. By placing two numbers on the subscribers' drop, one on the shutter corresponding with the answering jack, and one on the face-plate corresponding with the spring jack number in the multiple board, it is possible to make cross connections at the intermediate distributing board and not change the drop number of the subscriber.

A change of this kind will be effected as follows: Suppose that the operator upon which subscriber No. 654 terminates was very busy, and that the operator upon which subscriber No. 235 terminates was not so busy; and also that the subscriber No. 654 was a very busy wire, and subscriber No. 235 was not a busy wire, it would be desirable to interchange the answering jacks of these two subscribers, for by so doing the work of the operators would be more equally divided. This would be done at the intermediate distributing board by cross-connecting the two answering jacks and by changing the face plates on these two subscribers' drops. The office record of circuits should be so constituted as to admit of this dual numbering of drops.

The double track system for intercommunication between offices is recommended. Push buttons connecting local operators with the talking circuits are to be placed within easy reach in front of each operator. All in-coming trunks should terminate on single cords, and be operated by a call wire system. For this purpose the incoming trunk line operator has his head telephone included in the talking circuit from the other exchanges. The trunk circuits should be arranged so that if the calling wire breaks down, any other trunk line may be quickly substituted, and pending the change, the trunk lines operated by drops. It is also desirable to have the circuits so constructed that when the operator at the originating office disconnects a trunk line, the operator at the receiving office is notified automatically by special signal. This reduces the number of calls on the talking circuit one-half.

In front of the switchboard, in such a position that all sections may be easily seen, a monitor desk should be placed. This desk should have, terminating on spring jacks, loops extending to each operator, to the chief inspector's desk and to circuits in the mul-

tipale board. All operating rooms should be carpeted with linoleum to prevent noise by people walking about. On the same floor as the operating room a cloak room and lunch room should be provided. The lunch room should be equipped with tea and coffee urns, lunch table, &c. By providing such conveniences for the operators a better class of women become available and exchange service correspondingly improved.

In closing these remarks I would call attention to the necessity of providing complete working plans and specifications of the proposed equipment, including the cable run, before the construction of the building is commenced. Extensive alterations in buildings and apparatus already made in several of our central offices would not have been necessary had this been done. Such plans are as necessary to the successful and economical erection of a modern telephone exchange as are the plans for the erection of a suspension bridge or other engineering work.

In the discussion which followed the reading of the paper, Mr. CARTY, gave his views briefly on the subject of "Bridging Bells" This is a system of looping, the idea being if you had more than one station on a line to loop the intermediate stations in solid. It was found that a magnet in a line had something in it besides the mere resistance to the copper. The fact that your wire is coiled around on a core offers a resistance to the telephone current a great deal more than that represented by the number of ohms of wire. In nearly all of the lines that are constructed with more than one station looped down, the talking is very poor. A line was built in New York containing eight miles of underground cable and four miles of overhead wire and 10 stations looped in solid, and it was impossible to talk over it. The bridging bells were put on that line, and the talking over it now is as near perfect as it could be. It is impossible to tell the difference between a line having 10 stations on it and a line with only two stations. Mr. Sabin, of San Francisco, procured eight of the bells and put them on a line running from San Jose to San Francisco. The line had eight stations looped in, and it had been impossible to use it for through business at all, and talking to the way stations was very poor. But having equipped the line with these bells, he reports that it is impossible to tell the difference between talking on the way line and talking on the through line, and says that the induction on the way line bridged in this way is less than it is on the through line. So that actually it has turned out that the line works better with eight stations on it than it did with only two. This line is of iron, and is a grounded circuit, and these bells are simply bridged in or legged on. When lines are constructed on the bridge or multiple arc system, the construction of the wire is made much simpler. There is no bottom contact on it, and the bell rings equally well, whether the telephone is on the hook or off. In looking at some railroad troubles in Albany, I found that the drops were down and the business was paralysed. Mr. Pickernell made a suggestion that I take up some double-wound resistance coils and put them in between the drop and the ground. I did so, and that was a perfect remedy, and we ordered 50 of them and fixed it. While there it occurred to me that a bridging bell would act even better. I sent one up and it freed that line from the drop trouble. The particular bell that has been designed for this work has had introduced into it some mechanical improvements that are also applicable to the series bell. We have nut-lock binding posts, and wherever a wire was fastened by a tip these posts were put on and the wire was soldered. The lightning arrester was also taken off, because you might as well paint one on there as to use the present one. The lightning arrester forms a point generally where a fire starts. That bell was prepared with that in view, and if lightning protection is wanted it should be provided by the most approved plan and forming a part of the general scheme of protection against any currents. I think that is briefly all there is to it. In substance, it is, that if anybody here has a line with a lot of stations on it that is not working well, if he orders some of those bells they will make it work well. The Boston people have used some of the bells, and have constructed a fifteen station line for the Armstrong Transfer Company, and they reported to me that, taking the old line at one the working of the new line might be placed at 300. The working of this system in New York has been very gratifying. We started with the New York Central Railroad and reconstructed their ticket line and equipped it with bridging bells: Then the freight people heard about it, and now the result is that we have 40 stations on three lines for that company.

A MEMBER: Are those metallic or grounded?

MR. CARTY: Those are metallic. This practice is quite different from the ordinary looping practice. For instance, in the American Express Company—who made a big contract with us to equip them in the same way—they moved one of their stations, and we sent one of our men up and he took out the telephone, and, as had been his custom, he twisted the two ends of the wires together. That was a correct thing for him to do, as far as he knew. But it had the result, as you see here (illustrating on diagram) of just throwing the whole line out by short-circuiting it. Another man, in putting in a bridging station, drove a tack which crossed two wires together, and that prevented its bell from ringing. He started round looking for an opening, whereas he should have looked for a short circuit. So that this practice is diametrically opposed to what he had been used to. The question of an individual bell should not be confounded with this. The first thing is to get a line over which he can talk. After this is done, then that old saw of individual bells might come up again. You provide signals, and all of the stations are signalled when anybody rings. The construction of that bell is very little different from some

other bells that are made to do the work, but when you come to use 10 or 15 stations on a line you have got to have exactly that construction, and it is such an important matter to the licensees that we are making great efforts to get a patent on it. In designing that we not only have an idea of our immediate wants, but we wanted to get a bell that we could say would work on any line. Take a line with 20 stations. They are building a line now 40 miles long, of copper wire, and to be equipped with 20 stations.

Mr. GIFFORD: It would be very easy to arrange that, just as the district messenger people do with their calls coming in.

Mr. BAILEY: I want to say with reference to that system, that while the idea of telephone service is supposed to be the supplying of subscribers with an individual or single circuit, that is, a circuit on which but one telephone is placed, yet the conditions are such in a great many parts of the country, and particularly with corporations, that you cannot persuade them that it is the kind of service they want. These corporations are those that have been accustomed to telegraph systems, and they imagine that when they have a system which they can reach individually, without the intervention of a central office, that they are getting very much better service. It doesn't matter what our opinion is about that, when you try to bring those people to your way of thinking, you will find it very much of an uphill job, and the next thing to do is to accept the conditions and accommodate them. That can be done by a system of that kind. There is another advantage in that system which I think will be available in the future, and that is in the way of giving cheaper telephone service on metallic circuit lines to residences. The chief difficulty that I see about that system is on long extended lines, the liability that you have of damage to the apparatus by lightning. Our company have had for a number of years a system similar to that in operation on quite a number of lines. We have arrived at it by running a shunt wire, commencing at the first station out from the exchange. This shunt wire is passed in through the station, and the calling wire is looped through. The operation of that is, when a call has been made, the removal of the telephone opens the caller's circuit and lets the talking circuit from the earth through the shunt wire, thereby giving a free and independent wire for conversation. The talking over those lines has been magnificent. We get rid of the resistance of the coil through the circuit. I wanted to ask Mr. Carty if he found any of the effects of those coils reached the earth, as against the talking circuits. In the operation of those lines of ours we have found that in a thunderstorm the usual accidents we had were from lifting the switch and turning out the induction coils or the transmitters. That we obviated by putting a bridge there which shoves the switch to the earth, so that the current more readily passes through this direct wire than through the induction coil. I do not know whether, in this system, the ringer coils would not be subject to destruction. I think possibly there would be considerable trouble in that respect. However, it may be met by introducing some device. I should say that high resistance coils are more susceptible to damage by lightning, and when you take a line of that kind working in the country, it means stations far away and hard to reach, and therefore expensive, and a long interruption to service.

Mr. GIFFORD: That is a kind of business that it is not desirable to take.

Mr. BAILEY: But it is a kind of business you are obliged to take.

Mr. GIFFORD: I try to dodge all of that kind of business that I can.

Mr. BAILEY: But I should say, in Mr. Wilson's case in Chicago, he will find service of that kind that he cannot ignore. You must accept the situation, and devise something that will meet the demand.

Mr. GIFFORD: I do not wish to be considered as throwing any cold water on this system. I hope they will perfect their bridge bell and get a patent on it, but I do not see how it will work in all localities. Perhaps in some localities it will do. I would not know what to do with it—for instance, if I tried to use it for residence service. We make a cheap rate—all our rates are cheap (laughter); we make a cheaper rate to get some residences. You see, in Louisville, the residences are over on one side of the town, and the business portion of the city is on the other, and we debated whether we should cultivate that trade or not. At last we made a cheap residence rate, two and three subscribers on a line. Now, the Louisville woman don't want any other woman listening on her line, and they raised so much of a row that we had to do away with it.

Mr. BAILEY: Then you have had the advantage of educating those people to something better?

Mr. WILSON: Reference has been made to this question in Chicago. At one time we had quite a number of very long private lines, and the stations having been added one at a time that condition of things was permitted to go on until we found that we had a good deal of very unsatisfactory private line service. About a year ago we established a rule that we would not take any more private lines with more than five stations upon them, and we have succeeded in getting our private line business on that basis, and where a larger number of stations was required we have put in what we call our branch exchange service. For instance, the West Side Street Railroad Company have a private line of that description. They have their own exchange and their own operators. It costs them more money than it would to have a line run into our exchange at \$125 a year each, although we give them a reduction in the rate. The expense of operators to them makes it a little more than they would have to pay us. In that way we have entirely eliminated the long line private wire diffi-

culty. Now, the only objection that I see to the bridging arrangement on grounded circuits is the difficulty in locating troubles on the lines. We have been bridging our clearing-out office in Chicago for about two years, and find a great improvement. We have some very long underground lines, through cable, which were laid in the early history of the underground business, and with no margin for conversation at all. When we came to inserting the clearing-out drop in the old way it made conversation entirely impossible. After we re-wound our clearing-out branches with 300 to 500 ohms it brought the talk right up. So that I am well satisfied that the bridging scheme is the proper thing. But if you can avoid the bridging scheme and have independent lines, it is still better.

Mr. HIBBARD: This bridging-in question is a very important one. In Buffalo we have been doing a good deal of metallic circuit work for the last two years, and we had a good many combination lines, or party lines, which, after the electric lights were in operation, gave very poor service. We commenced this system of bridging-in with one or two more subscribers on a line, using first the ordinary bell, which gave us of course very poor service. Then we put in 500-ohm ringing coils. With that system and with 500 ohms in the central office, we are getting first class service with five and six on the line. We have also quite a number of private lines used by railway companies, where they have as many as eight and nine stations on the line, bridged in with 500-ohm bells, and those stations are giving splendid service.

Mr. WILSON stated that they were operating all the transmitters in the main office of the Chicago exchange with the Edison current, and are accomplishing good results. We use storage batteries. We are using at present five cells of storage batteries, which have an electromotive force of a little over two volts per cell and gives out about five amperes of current. The five cells are connected directly with the Edison current which supplies the office with light, and the storage takes place when we burn the light and we do not observe any diminution in the lighting throughout the building. There is, therefore, no expense for current. The internal resistance of each cell of the storage battery is about two-hundredths of an ohm. Consequently, as you add transmitters, it simply absorbs more current than the storage battery. The object of having five cells is that it enables us to maintain the storage battery throughout the 24 hours without its becoming exhausted. If we connected all the transmitters we would necessarily have to turn on light during the day to recharge them. Our experience has shown that with five cells it works entirely automatically. We supply between 60 and 70 transmitters.

Mr. GIFFORD: How many transmitters will one cell energise during 24 hours?

Mr. WILSON: The arrangement we have contemplates 100 transmitters. We are only operating 60.

Mr. BAILEY: How many transmitters do you couple on to one cell?

Mr. WILSON: At the present time it is about 12, and we adjust the resistance until the current in each transmitter is all that it will stand. We use the Edison current for ringing instead of the small generators.

## NEW PATENTS—1890.

14927. "Improvements in telephones." G. MACAULAY-CRUIKSHANK. (Communicated by E. B. Welch, United States.) Dated September 22. (Complete.)

14974. "Improvements in electric meters." W. T. GOOLDEN and S. EVERSHED. Dated September 22.

15043. "Improvements in electric heating apparatus." W. R. LAKE. (Communicated by E. Abshagen, United States.) Dated September 23. (Complete.)

15061. "Improvements in electrical apparatus for the prevention of corrosion, and formation of scale in steam boilers." J. TELLEFSEN. Dated September 23.

15084. "Improvements in electric railway conduits with tubular conductors." C. J. VAN DEPOELE. Dated September 24. (Complete.) [Date applied for under Patents Act, 1883, Sec. 103, 22nd May, 1890, being date of application in United States.]

15114. "Improvements in the manufacture of plates for secondary batteries, and in the construction of such batteries." G. C. FRICKER and J. R. BAINTON. Dated September 24.

15165. "Conveying additional telegraph or telephone wires over houses and other different places after one wire or cord has already been stretched." W. J. PARKER. Dated September 25.

15191. "Improved process or method of renewing flexible carbon filaments in glow or incandescent electric lamps." C. PAUTHONIER and L'INCANDESCENCE ELECTRIQUE SOCIETE. Dated September 25.

15203. "An improved socket for incandescent electric lamps." H. H. LAKE. (Communicated by J. S. Potter, United States.) Dated September 25.

15221. "Improvements in the production of electric currents by means of air or water for lighting steamships and railway trains, and for other purposes." P. R. DE F. D'HUMY. Dated September 26.

15248. "Improvements in dynamos and electric apparatus for charging accumulator cells and running lamps at the same time."

W. B. SISLING, W. H. SCOTT, and LAURENCE, SCOTT & Co., LIMITED. Dated September 26.

15249. "Improvements in the manufacture of electrical conductors." A. MUIRHEAD. Dated September 26.

15250. "Improvements in and relating to the electric circuit connections used for lighting theatres and for analogous purposes." H. SOUTH. Dated September 26.

15251. "An improved supporting base for electric lamps and conduit for conductors therefor." H. SOUTH. Dated September 26.

15252. "An improved holder for incandescent electric lamps." H. SOUTH. Dated September 26.

15274. "A method of, and appliances for automatically utilizing any excess of electricity generated for electric lighting and other purposes, and for automatically supplying any deficiency." E. B. BRIGHT and F. W. ENGELBACH. Dated September 26.

15328. "Method and devices for heating by means of electric currents." C. ZIPERNOWSKY. Dated September 27.

15337. "Improvements in or relating to electric alarm bells." J. B. M. BONNARDOT. Dated September 27.

### ABSTRACTS

#### OF PUBLISHED SPECIFICATIONS, 1889.

7165. "Apparatus for electrical distribution of energy." J. M. MUNRO. Dated April 30. 8d. Relates to the use of high tension continuous currents or varying strength with transformers in series or parallel. 2 claims.

8493. "Improvements in automatic cut-outs for electrical circuits." W. J. STARKEY BARBER-STARKEY. Dated May 22. 8d. The inventor includes a small dynamo or magneto-electric motor in a high resistance shunt from the dynamo or mains. By means of stops or other devices he limits the possible angular motion of the armature of this electro-motor, so that it may not rotate continuously whilst its circuit is closed. The spindle of the armature is geared or connected with a switch or device such as a mercury or brush contact, for opening and closing the main circuit. If it is required that the apparatus shall close a circuit as soon as the pressure reaches a certain amount, the force which opposes the rotation of the armature is regulated so that the armature can move only when that pressure is reached. If it is desired that the circuit should be opened as soon as the current reaches a predetermined pressure, the force opposing the rotation of the armature is regulated so that the armature will not move until that pressure is reached; in this case the main circuit is already closed, and the apparatus operates to open it; in the former case the reverse happens, that is to say, the circuit is already open, and the apparatus closes it. When the armature of the motor moves in consequence of the pressure having reached a determined amount, the motion of the armature is communicated by the connecting device to the switch or contacts, so as to open or close the circuit as hereinbefore described. When it is desired to open the circuit, if more than a determined pressure exists in the main, the motor may have one or more coils of thick wire included in the main circuit. 7 claims.

8780. "Improvements in electrical switches or cut-outs." E. E. DE FACIEU. Dated May 27. 8d. Consists essentially of a contact piece, which once set to the position of "closed circuit," is held down in that position by magnetic attraction, which magnetic attraction ceases as soon as the current conveyed by the switch increases by a definite quantity or percentage; the contact piece being then released, automatically reverts to the position of "open circuit," and stops the current. 2 claims.

8815. "Improvements and devices for automatically interrupting an electric circuit under predetermined conditions." W. P. THOMPSON. (A communication from abroad by the Westinghouse Electric Company, of America.) Dated May 28. 8d. Is designed to provide a circuit-controlling device which shall insure that the circuit leading to the filaments shall be interrupted, and the treatment thereof terminate when the resistance of the filament has decreased to a certain predetermined point. 3 claims.

12970. "Improvements in printing telegraph instruments." J. E. WRIGHT and J. MOORE. Dated August 16. 11d. According to this invention the type wheel is turned in both directions, so that it never has to perform more than a half revolution, and it is brought back to zero after every printing operation. 6 claims.

13675. "Improvements in the arrangements and apparatus for electrically lighting railway trains." W. E. LANGDON. Dated August 30. 8d. Relates to the employment of an improved electrical coupling for connecting the several cables or wires through from vehicle to vehicle, and for automatically, under certain conditions, connecting together and disconnecting certain of the said cables or wires. And in the employment in connection with certain of the said cables in each vehicle electrically lighted, where the system of electric lighting is that known as the "parallel" system, of an electrical resistance automatically operated so that when the current from the dynamo is in operation, the said resistance shall be thrown into the lighting circuit of the said vehicle, and when the current from the dynamo is not in operation, the

said resistance shall be cut out of the lighting circuit. Also in the employment upon any electrically lighted vehicle, of a special device for the purpose of enabling the electrical condition of the batteries or accumulators of the said vehicle to be readily ascertained, and for providing against injury to the batteries by "short circuiting" at such points. Also in making suitable provision for obtaining ready access to the electric lamps for cleaning and for other purposes. 8 claims.

### IDENTITY OF STRUCTURE BETWEEN LIGHTNING AND THE DISCHARGES OF INDUCTION MACHINES.

DURING the storm which burst over Meudon on May 8th, 1890, at about half-past six in the evening, the flashes of lightning, which were frequent and very high, took in nearly every case a horizontal direction; later on, when the rain had commenced, they were vertical, darting from the cloud to the horizon. The horizontal flashes were distinguished by a well-defined arborescent form, the numerous ramifications of which were lost in the cloud. For the most part they appeared singly, but between 6.50 and 7.10 in several instances two were seen at once, coming to meet one another from opposite directions.

One of these pairs of flashes, which subtended an angle of more than 90°, appeared in front of me, under conditions peculiarly favourable for observation. They appeared simultaneously; two separate points of the cloud were lighted up at the same instant, and two dazzling masses of light darted towards each other dividing into several branches, which in their turn were subdivided into smaller ones. The meeting, which seemed inevitable, did not, however, take place; although the extremities of the opposite branches were only separated by a space of less than 10°.

These flashes, writes M. E. Trouvelot to the *Academie des Sciences*, which lasted long enough to enable one to see clearly the form they took, were a revelation to me. It was no longer two flashes of lightning that I saw, but two electric sparks, absolutely similar, except as regards their magnitude, to the sparks of induction machines, which have become so familiar to me by long study, that I can recognise their characteristics at a glance.

In these arborescent forms, I noted that the one which came from the north, against the wind, and the branches of which were sinuous and undulating, had the appearance that is characteristic of the discharges of the positive pole of induction machines, whereas the one that came from the south, in the direction of the wind, and the zigzag branches of which deviated abruptly at right angles, had the appearance that characterises the discharges of the negative pole.

My observations seem to me conclusive; they show that in certain storms, which I will term *dry storms*, the electric discharges termed *lightning* act almost like those of our machines on bodies that are only slightly conductive, and have almost the same structure. If even there were any doubt about the characteristic forms which I observed, the very fact that two branched flashes advance towards one another and almost meet, is sufficient to prove that the sources of electricity which provoked them must be of contrary natures.

On the occasion in question, I could only observe very imperfectly, on account of its great distance, the flash uniting one cloud to another, or to the earth, by a line of fire. However, judging by analogy, and what I have observed since, and also by the examination of several photographs of flashes of lightning, there seems to be no doubt that this kind of lightning corresponds to the discharges of the opposite poles of machines, when they are united by a powerful spark.

From these observations it follows: 1st, that the arborescent flash electrifies the cloud by discharging itself upon it, as the discharges of machines electrify the sensitive plate; 2nd, that it can go down or up, horizontally or obliquely, in short, that it may take any direction; 3rd, that it varies in form according as the

storm is dry or accompanied by rain, and is more complicated in the first case. Lastly, the arborescent and complicated form of the flash not appearing on one plane, but at variable distances, explains the characteristic noise of thunder.\*

### A NEW SAFETY LAMP FOR MINES.

Note by M. CHARLES POLLÁK.

(SUBMITTED TO THE FIRE DAMP COMMITTEE.)

THE following is a brief description of this lamp :—

A rectangular box of ebonite contains some accumulators of the Pollak type;† this box rests on a metal tray. An ebonite lid serves as a support for an incandescence lamp, which is enclosed in a cylinder of thick glass. The whole is covered with a metal cap, fastened by means of bolts. A sheet of soft gutta-percha, interposed between the lid and the box, closes it hermetically. Rods of inoxidisable metal are inserted in the lid, passing right through it; at their bases are platinum contacts which rest upon platinum contacts in the accumulators, and at their other extremities are springs, one of which is connected metallically with one foot of the lamp. The other foot is insulated, and can be brought into contact with one pole of the accumulator by means of a needle which is introduced into a horizontal groove in the lid.

The contacts being on the inside of the box and the lid, neither the opening nor the closing of the circuit can cause any explosion. Thus the lamp may be lighted or extinguished in an inflammable atmosphere. If the system is thrown out of working order, or if the protecting glass cylinder is broken, the lamp is extinguished.

The lamp is charged, without being taken to pieces, by means of a fork, which is introduced into two grooves hollowed out in the lid.

The model in existence weighs about 1,800 gr., and gives, on an average, 12 hours of perfectly constant light, the power of which = .7 to .8 of a candle-power. —*Comptes Rendus.*

### CORRESPONDENCE.

#### Electrical Heterodoxy.

I am glad Mr. Sutton has come to the conclusion that a continuance of this correspondence would be a waste of your valuable space. Other duties occupy all my present time, but if spared I intend writing an article which shall be headed *What is Induction?* And in it this whole subject shall be embraced. In the mean time, I ask Mr. Sutton to bear in mind that when Faraday abandoned the theory of action at a distance he saw the necessity of devising something as being the cause of the various phenomena to which he gave the name of *induction*. For this purpose he invented the idea of two electric forces. To the action of these two forces he attributed all the effects which he called *induction*. Whereas in Mr. Sutton's first letter he gave a diagram and explanation of it, which showed that he believed in that which Faraday called induction, and yet Mr. Sutton maintained that there was no need to believe in Faraday's two forces. If Mr. Sutton had proceeded to state something as a substitute for

\* Photographs of direct discharges of electricity from the cloud to the sensitive plate might prove of great service in the study of lightning. We have already made some attempts in this direction, but unsuccessfully, with a captive balloon which had been kindly placed at our disposal by Commandant Renard, whom we take this opportunity of thanking. Experiments of this nature would no doubt have greater chances of success, if they were made at elevated parts of the globe.

† Presented to the Academy, March 17th, 1890.

Faraday's two forces all might have been well, but he did not do so, and therefore left others to conclude that he believed that an effect might be produced without a cause.

This is only one of the fundamental errors about electricity contained in Mr. Sutton's first letter which, if I had answered fully, would have led to a lengthened correspondence, which would have occupied uselessly much of your valuable space. If Mr. Sutton will not read in private a book that will give him much-needed information about electricity, he cannot expect that his lucubrations about electricity will be answered in the public prints.

Mr. Sutton is wrong in his surmise about the insulated gas-flame test. In your leading article you expressed no doubt of the accuracy of this test, and all the various parties who have seen my experiments with it from the year 1839 till now have been convinced that I am right.

Pith balls and similar substances, when placed between two bodies between which a current of electricity is passing, always oscillate between the two bodies, and therefore pith balls give no indication of the direction in which the current of electricity is moving; but an insulated gas flame never oscillates—it always bends steadily in the direction in which a current of electricity is moving, and hence its value as a test.

James Johnstone.

13th October, 1890.

#### Mutual Telephone Company and Yorkshire Telephone Company.

Can you kindly inform me through your next issue how far the above companies are developed, and whether they have commenced actual work yet? Also, whether any other companies are applying for licenses?

Telephone.

October 13th, 1890.

#### The National Telephone Company and Muirhead, Glasgow.

In your last week's issue you refer at length to a letter of mine that appeared in the *North British Daily Mail*, Glasgow. My letter referred to several points, but I shall first refer to the one which you are sceptical of, as you do not think that the National Telephone Company could be guilty of such an act of tyranny as I impeach them with. I enclose herewith six original letters from the National Telephone Company, addressed to myself. In justice to me you will, I am sure, publish them, as they bear out my statement that the National Telephone Company's vice-chairman, Col. Jackson, and the chairman of the Glasgow Board, invited me to bring from France a number of Ader and Berthon Telephones, which they kept in their possession for about two months, then ordered me, on pain of an action at law, to return them. This I declined to do, but offered to send them to the Glasgow office; but as they did not at first accept this offer, I withdrew that also.

They then, in defiance of the clearest evidence, denied I had ever signed a contract for the use of their exchange telephone, which they removed without the usual six months' notice, though their own directory and other printed rules says, "every subscriber must sign a contract," &c.

They get their subscribers to sign contracts which they themselves keep, so that they can blow hot and cold with the same breath.

They have neither the courage to deny those statements I have publicly made nor the manliness to own themselves wrong.

The proposed demonstration will be with an *Ader receiver* and a *Gower receiver*, used as a transmitter, both of which I believe are free on 9th December. With this Ader receiver you can hear though some

yards from it, when speech is transmitted by a Berthon transmitter.

A. Erskine Muirhead.

14th October, 1890.

The National Telephone Company, Limited.  
Glasgow Offices, Royal Exchange Buildings,  
13th March, 1890.

A. E. Muirhead, Esq.

Dear Sir,—Referring to your interview with Col. Jackson and myself this morning, I shall be pleased if you will send on to London two Ader receivers, No. 3 in your catalogue, and four of the same, here, and two of the Poste Berthon transmitters, No. 117 in your catalogue, to London, and four of the same here.

The above to be sent on loan for trial here and in London.—

Yours truly, WM. ALEX. SMITH,  
Chairman of Glasgow Board.

The National Telephone Company, Limited,  
Glasgow Offices, Royal Exchange Buildings,  
9th June, 1890.

A. E. Muirhead, Esq., Cart Forge, Crossmyloof.

Dear Sir,—I am much obliged to you for the loan of the French instruments, which I now return. Please receive herewith three Ader receivers, two Ader transmitters, two Berthon transmitters and one Berthon-Ader combined with magneto.—Yours truly,  
W. AITKEN, Engineer.

The National Telephone Company, Limited,  
Oxford Court, Cannon Street, London, E.C.,  
25th June, 1890.

A. E. Muirhead, Esq., Glasgow.

Dear Sir,—We are in receipt of your letter of 24th and also of "Gower" instrument. This instrument is a distinct infringement of our patent rights, and by importing it you have rendered yourself liable to proceedings for an injunction and for damages. As you have sent the instrument evidently in good faith we return it to you, but at the same time we must insist on your returning it and any other similar instruments to France forthwith, or we shall have to institute proceedings against you, and we shall require a declaration from you that this has been done.

As I mentioned to you in mine of 11th inst., we cannot see our way to accepting your proposal as to royalties. I must also inform you that we do not sell any instruments.—Yours faithfully,

T. BLAICKIE, Secretary.

The National Telephone Company, Limited,  
Oxford Court, Cannon Street, London, E.C.,  
5th July, 1890.

A. Erskine Muirhead, Esq., Glasgow.

Dear Sir,—We are in receipt of your letters of 26th and 28th ult., and in reply have to state that we cannot have the telephones left in Glasgow, but must now ask you to send them up to us here within a week.

You are quite in error as to your being able to do as you choose in December next, as stated in your letter of 26th ult., so far as our patents are concerned.—Yours faithfully,

T. BLAICKIE, Secretary.

The National Telephone Company, Limited,  
Oxford Court, Cannon Street, London, E.C.,  
19th August, 1890.

Mr. A. E. Muirhead, Glasgow.

French Telephone Instruments.

Dear Sir,—With reference to previous correspondence in this matter, we must ask you to be good enough to send these instruments in to our Glasgow office, in compliance with your offer to do so contained in your letter of 28th June, 1890.—Yours faithfully,

A. ANNS, for Secretary.

The National Telephone Company, Limited,  
Oxford Court, Cannon Street, London, E.C.,  
29th August, 1890.

A. E. Muirhead, Esq., Glasgow.

Sir,—As we have no reply to our letter of 19th inst., I have now to inform you that unless we hear from you on or before Wednesday next, 3rd September, we shall instruct our solicitors to proceed in the matter without further notice.—Yours faithfully,  
ALBERT ANNS, for Secretary.

#### A Phenomenon; indeed!

Will you please explain the cause of a phenomenon which occurred the other day? I was filling up some 23 L accumulators (new positive plates) with the usual solution of dilute acid, and the liquid was not particularly clean, so I put an iron gauze strainer across top of plates

This gauze was touching both poles of the cells, and when the acid reached it—the glass being then nearly full—a perceptible fusing was noticed between edges of gauze and poles of accumulator. Is this due to an electrical or a chemical action?

An answer will greatly oblige, and receive the thanks of

Hypothesis.

October 13th, 1890.

[If the gauze made a short circuit between the poles of the cell, we do not know what other result could be expected than the fusing of the metal. The fact that the occurrence did not take place until the acid reached it appears accidental only.—EDS. ELEC. REV.]

#### Candle-Power of Electric Lamps.

In your issue of the 3rd inst., you drew attention to the exaggeration of candle-powers in arc and incandescent lighting.

With arc lighting, I think most engineers take account of this and allow somewhere about 600 effective candle-power for an arc of 2,000 nominal C.P., as in the tests carried out at Berlin, but with incandescent lighting little or no reduction is needed.

As a matter of general interest I send you the results of some tests carried out at the Vienna Central Station in 1888. The lamps burnt out at the two Court theatres were replaced by the company, and as these amounted to somewhere about 25,000 per year, it was of the greatest importance to choose between the different makers. Five of each make were taken, and lighted from a constant pressure of 100 volts, the pressure of the lamps, the current being taken from a reserve battery and the pressure exactly adjusted. Each day the lamps were taken out singly and measured on the photometer, filament broadside on, and the sum of the candle-powers of each make plotted out.

#### Lamp Curves.—Watts per Candle.

Hours burning.	Swan.		Allgemeine Electric Ges.		Siemens and Halske.		Edison-Paris.		Khotinsky.	
	C.P.	Watts.	C.P.	Watts.	C.P.	Watts.	C.P.	Watts.	C.P.	Watts.
100	18.8	3.45	16.3	3.31	14.3	3.41	32.8	4.15	13.8	3.6
200	17.2	3.79	14.3	3.66	12.3	3.84	28.1	4.85	12.5	3.79
300	15.6	4.1	13.4	3.87	11.1	4.2	26.3	5.25	11.2	4.22
400	15.2	4.17	11.8	4.33	10.5	4.33	23.2	5.9	9.6	4.75
500	14.8	4.29	11.1	4.59	9.7	4.74	21.0	6.5	9.4	4.8
600	14.4	4.38	10.1	5.01	9.3	5.01	16.5	8.3	8.9	4.98
700	14.1	4.5	8.9	5.51	8.3	5.36	—	—	7.8	5.49
800	13.3	4.68	7.8	5.79	7.8	5.67	—	—	6.9	5.96
900	12.4	4.9	8.0	5.9	7.1	5.95	—	—	6.6	6.1
Average.	15.1	4.25	11.3	4.66	10.05	4.72	24.7	5.83	9.6	4.85

If a lamp broke it reduced the total height of the curve. The splendid instruments in the possession of this station ensure the reliability of these figures. Allowing for improvements in the Edison-Swan Company's manufacture during the last two years, and taking the mean candle-power as representing the mean effective illumination of a building, I think one can fairly speak of a 16 C.P. lamp at  $4\frac{1}{4}$  watts per candle with a life of 1,000 hours.

The fact of the matter is, that the present 16 C.P. lamp is the old 20 C.P. nominal. Mr. Preece, I believe, has made some valuable experiments in gas lighting at the General Post Office, which would bear on the case as regards the behaviour of gas burners under similar conditions.

S. T. Dobson.

October 14th, 1890.

WE have received a letter on "The Labour Question," but as the writer does not favour us with his name and address we hold it over. Perchance our correspondent may think fit to conform to our custom, and his communication will then appear in due course.

## THE CURRIE STORAGE BATTERY.

ABOUT this time last year we published an article from the pen of Mr. A. Reckenzaun on the secondary batteries shown at the Paris Exhibition. Among them was the Laurent-Cely accumulator, exploited and constructed by the Société Anonyme pour le Travail Electrique des Méteaux. The special feature of this invention consists in the nature of the active material, which is a mixture of chloride of lead and chloride of zinc. The fused chloride of lead has a density of 5.6; by incorporating chloride of zinc with it in certain proportions the density is reduced to 4.5. This mixture, brought to a state of fusion, is run into cast-iron moulds in the form of small buttons with rounded edges. When cool, the buttons are washed to remove the chloride of zinc, whereby a porous mass is obtained. Round these buttons is cast a frame of lead and antimony, when the plate is ready for formation. The negative plates are next placed in cells containing acidulated water, together with zinc electrodes, and charged. The hydrogen which is disengaged upon the positive electrode reduces the chloride of lead, and converts it into the metallic state.

A somewhat analogous process is used by Mr. Stanley C. C. Currie, of Philadelphia, and this is fully described in a recent number of the New York *Electrical Engineer*.

Commercial lead is first finely divided by a special process. This is dissolved in nitric acid and then precipitated as chloride of lead by the addition of hydrochloric acid. The white chloride of lead so obtained, after being thoroughly washed and dried, is mixed with a certain proportion of chloride of zinc and the mixture brought to a molten state in a furnace. The fused mixed chlorides are then poured into square moulds and allowed to cool. They are next placed into another mould prepared for their reception and a grid of lead cast around them, binding the blocks into a compact plate. The molten lead is forced around the blocks under pressure in order to ensure the best pos-

sible contact. The plates thus produced are then packed between zinc plates and placed into a tank containing a dilute solution of chloride of zinc. There is thus formed a voltaic couple, the action of which is to dissolve the zinc chloride and to extract the chlorine from the lead chloride, leaving spongy lead in its place. The last trace of chlorine is then removed from the plates by washing and then placing them in a tank containing nitric acid, and passing a current through them. The plates intended for anodes (positives) are formed into peroxide in dilute sulphuric acid.

The standard cell contains 9 positive and 10 negative plates, weighing together 34 lbs., and giving a capacity of 230 ampère hours; the plates are  $5\frac{3}{4}$  inches wide and 6 inches high.

The Germantown Electric Light Company, Philadelphia, uses 512 of these cells, arranged in 8 series of 64 each, having a combined capacity of 1,600 ampère-hours.

Mr. Currie has also designed several novel automatic devices used in connection with this storage battery plant. Among these is a "full-charge indicator," which consists of two strips of lead attached to a strip of ebonite. The upper ends of the lead strips carry a pair of binding screws and wires leading to an electric bell, whilst the lower ends of the lead are bent one over the other in such a manner as to leave a small air-space between them. The whole is suspended above the liquid of any cell. As soon as the battery is fully charged it begins to "boil," due to the rapid development of gases. This creates a spray of acid, which is projected upward, and some of it accumulates on the lead strips referred to until it forms a drop of liquid bridging the small gap between the two strips; circuit is thus established for the bell to ring, and notify thereby the attendant that the charging is complete. This device is, however, used in connection with an automatic cut-out, constructed on the usual electromagnetic principles. There is also an automatic apparatus for preventing reversals of polarity.

The Electric Car Company of America has been

testing Mr. Currie's storage batteries on four of their tramcars on the Lehigh Avenue Street Railway, Philadelphia, during the last four months. There are 100 cells, of the railroad type, on each vehicle. During the month of August 59,000 passengers were carried on this road, which has numerous curves and grades as heavy as  $5\frac{1}{2}$  per cent., whereby the batteries have been taxed to their utmost, the load on a car consisting, at times, of 100 passengers.

## THE ELMORE PATENTS.

No. 10,720, 1884. This patent refers to the construction of moulds in segments, with suitable patterns engraved or embossed upon their inner surfaces, upon which copper or other metal is electro-deposited, and the resultant used as rollers for printing or embossing patterns either on paper or other substances.

No. 1,737, 1885, is an improvement in detail on the 1884 patent for segmental moulds which can be easily removed from the deposited metal and re-used. The purposes of such moulds are not limited to the production of printing rollers, as in the previous specification.

No. 4,499, 1885, is for a core or mould of a metal or alloy whose expansive or contracting properties shall differ from that of the metal deposited, thus facilitating its removal under proper treatment from the deposited metal. Also for the employment in the solution or bath of a burnisher. Three methods of burnishing are shown—by a travelling tool, by continuous pressure, and by an oscillating movement. The claims for the burnisher are limited to its application within the solution of the bath. The reason for this is plainly set forth in the patent in the following words:—

"It is well known that when almost any metal is deposited electrolytically from its solution the deposit is more or less crystalline, and that this crystalline nature of the deposited metal increases to a certain extent with the increased action of the current, therefore I employ the process of burnishing carried on simultaneously with the process of depositing, without removing the mandril with its deposit from the solution or out of a solution, and so the deposited surface is burnished without bringing it into contact with the air, and I carry on these two processes substantially as set forth."

No. 8,707, 1885, is for a system of making copper tubes by a combined electric and drawing process—that is to say, the preliminary formation of a block or "use" is by electro-deposition, this block being drawn down over a mandril through dies in the usual way; also the particular process described for freeing the tube from its mandril; and the manufacture of corrugated or spiral tubes by depositing the metal upon a core whose corrugations are of a screw-thread form, and this mandril, after a particular treatment described, can be withdrawn from the tube.

No. 10,451, 1885. This patent applies the burnishing principle to metal articles, such as pans, containers, and

the like. It protects the combination of a rotating core with burnishers. The claims do not expressly submerge the burnishers, but the drawings do.

No. 11,800, 1885. This patent, an improvement on the four foregoing inventions, relates to a process for the deposition of copper in the manner described in previous patents, and for simultaneously refining impure copper, or extracting the metal from its ore. The economy of this is shown in the specification by the statement that the two things are done at "practically the same cost as would be incurred in carrying out either process separately."

No. 9,214, 1886. This patent applies the burnishing process to the covering of plates, wires, &c., or the deposition of metal into the form of sheets or bands. It introduces a revolving burnisher, and it claims the use of an endless band surface, or a continuous drum surface of lead coating or alloy, for receiving the initial deposit.

No. 16,637, 1887. This patent practically claims the obtaining long continuous bands from electrically-deposited copper by any suitable method.

No. 11,778, 1888. This patent provides for the application of a rolling or hammering action on the deposited coating during the process of deposition, instead of the burnishing. For this purpose the mandril has to be partially out of the solution, and a cover provided which ensures the return to the bath of any portions of the deposit which may be hammered off.

No. 12,022, 1888. This patent claims to protect the method of depositing copper at very high temperatures, and simultaneously submitting it to mechanical treatment. It is claimed that tubes made in this way will be more suitable for use as steam pipes, &c., than as commonly made.

No. 12,264, 1888. This patent refers to the moulds or cores, and claims to cover the use of a coating of lead or tin, for the double purpose of filling up any crevices which may exist in the main core, whether consisting of a single piece or a combination of separate pieces, and of preventing injurious action of the solution in the event of the core being of iron.

It is not our intention to comment on these patents in detail. It will be seen that some of them are not very nearly related to the main question, whilst others are of a subordinate character.

Each is doubtless an improvement in its respective sphere, and may be of considerable value, but does not control an industry. Attention has been rightly directed more particularly to the burnishing process, commencing with 4,499 of 1885, and the improvements on the original plan, or its application to different articles, which follow in later patents. It is necessary to draw a distinction between a patent which enables a certain thing to be done in one of several ways, and a patent protecting an article or a process which cannot be obtained in any other way. Electro-metallurgy is a science of respectable age. Electro-deposition is not new. Patents, therefore, on these subjects are necessarily restricted to the particular processes described. For example, the essence of the Elmore process is the combination of electrical deposition with

mechanical treatment; but the patents must be limited to a particular form of electro-deposition, combined with a particular form of mechanical treatment, and a monopoly can only exist on the assumption that no other forms are practicable.

Supposing the Elmore process to be a valuable invention it will, according to all precedent, meet with imitators. There is an unfortunate tendency on the part of a large number of people to have a hand in a revolution if they can. In such an event the Elmore Company would rightly fall back upon its patents for protection, proceeding against trespassers with all the rigour of the law. Assuming the novelty of the process they might reasonably claim, and, in our opinion, deserve, a "benevolent" construction; but when it is remembered that in 1885 (No. 4499) the mechanical treatment was considered to be essentially conducted within the solution and so protected in the form of burnishing, whilst in 1888 (No. 11,778) the mechanical treatment was found to be possible out of the solution, and so protected in the form of hammering, there seems to be little room even for a benevolent interpretation should some evil-disposed person take the burnisher of one patent and apply it in the manner reserved for hammering in the other.

Considering the amount of money paid for these patents, and the extensive financial developments to which they have given rise, it seems surprising to have to record that they have not yet received that *cachet* of validity—extensive work and immunity from attack, nor have they been through the fire of the Courts and come through unscathed.

## THE ELECTRO-DEPOSITION OF COPPER.

IN last week's issue we referred to the various points involved in the electro-deposition of copper, and we laid before our readers certain details which were intended to enable them to form a more correct judgment on a certain process than had hitherto been possible except to the well-versed in electro-technical industries. We showed that in a German establishment the practical electro-deposition of copper involved an expenditure of 900 horse-power hours per ton, and that the daily output was 1,760 lbs. per day of twenty-four hours; approximately, about 5 tons per week of 144 hours.

In Dr. Hopkinson's report on the Elmore process, he estimates that with 60 tanks, working 161 hours a week, there will be produced 18,000 lbs. of tube, say 8 tons, and as our readers are already aware, the calculated cost of production did not exceed £5 per ton.

We have had several enquiries from the uninitiated public asking the meaning of Dr. Hopkinson's figures, for to some people it appears that the expression, "the net result of my observation is that a ton of copper can be deposited in steady continuous work by a consumption, with good engine and boiler, of less than 1½ tons

of coal, costing 8s. 6d. per ton," gives rise to the belief that this is the total cost for motive power.

Now the output of the two establishments named is sufficiently close to enable a comparison to be made, so if we take 900 horse-power hours at even so low a rate as ½d. per horse-power, we arrive at a sum of, say, £2 for motive power alone, but this sum would probably be doubled in practice.

When it is borne in mind that the electrolytic method of refining copper is carried on in various places under totally different circumstances, and that it is not to the advantage of manufacturers to make public the details of their processes for securing the most economical results, it is evident that any published data in this connection, especially when merely hypothetical, must be received with caution; but the following figures, given by M. Fontaine, if not absolutely correct, have the advantage of being derived from actual practice:—

Factories taken as examples.	Expenditure per ton of refined copper.					
	Interest on capital.	Motive power.	Maintenance.	Labour.	General expenditure.	Total.
	Frs.	Frs.	Frs.	Frs.	Frs.	Frs.
Hilarion Roux, Marseilles .....	78.80	112.00	18	72.00	108.0	388.8
North German Refinery, Hamburg .....	64.65	39.50	12	40.0	40.0	196.0
Elliott Metal Co., Birmingham...	35.95	180.06	30	57.75	57.75	361.45

"The cost of fuel in Birmingham," says M. Fontaine, "is much lower than we have taken as a basis, but taking it at 5s. per ton at the works, we find that the motive power still costs 125 francs per ton of copper. If we leave the other figures unaltered, we obtain a total of 306.45 francs, that is to say, a much greater expenditure than at the Hamburg works. The interest on the capital engaged represents a small proportion only of the cost price, whereas at Hamburg it constitutes the main expenditure."

When we take into consideration the large amount of what may be briefly described as dead capital, the cost of production would have to be low indeed to allow of anything like the high dividends pre-shadowed in the prospectus of the various companies, especially when it is remembered that the process is a new one, in which a good deal may have to be learnt and paid for before even wire can be supplied commercially.

Dr. Hopkinson is probably correct so far as his estimate of fuel is concerned; but if the data given above represents the real expenditure entailed in electrolytic operations, then it looks as if his calculation of £5 per ton must be trebled.

We will now turn to another phase of the Elmore scheme.

Amongst the advantages claimed for this process is that "the electrical conductivity of the annealed copper has a conducting power of 4½ per cent. above that of the best guaranteed commercial copper." This statement has evidently been made upon the strength of the report of Messrs. Clarke, Forde and Taylor, an extract from which appeared in the various prospectuses of the

Elmore Copper Company that have been placed before the public on different occasions, and to which we have already alluded. They state, "your annealed copper has a conductivity of  $4\frac{1}{2}$  per cent. above that of the best commercial copper." Now, in the prospectus of Elmore's Patent Copper Depositing Company, Limited, the conductivity of the copper was, if we rightly remember, stated to be 102 per cent.; it would, therefore, appear that Messrs. Clarke, Forde and Taylor have based their calculations on commercial copper at  $97\frac{1}{2}$  per cent., which is, according to English manufacturers, a very fair basis. In France, however, the well-known firm of G. O. Mouchel, which owns perhaps the largest and oldest copper manufactory in France, has for some years paid special attention to the manufacture of copper wire for electrical purposes, and as far back as 1885 it was commercially supplying copper wires with a guaranteed conductivity of 100 per cent.

At the Inventions Exhibition, held in London in 1885, Messrs. Davis and Timmins, Limited, who were, and still are, the sole agents in England for Messrs. Mouchel, exhibited a large quantity of wire, guaranteeing the conductivity to be not less than 100 per cent., and the firm has since that date been supplying large quantities of similar wire with the same guarantee. We have been assured by Messrs. Davis and Timmins that, although they only guarantee 100 per cent., the bulk of the wire will be found considerably over this. At the official tests made at the International Exhibition of Antwerp in 1885, it was found that annealed commercial copper wire manufactured by G. O. Mouchel had a conductivity of 104.15 per cent., with an elongation of 40 to 60 per cent. From the above facts, it is evident that neither Messrs. Clarke, Forde and Taylor, nor the directors of the Elmore Company, were aware of what had been done in France as regards the conductivity of copper, and this appears all the more strange, as for the last five years Messrs. Davis and Timmins have been, as agents for G. O. Mouchel, constantly advertising.

In the usual contracts for copper wire for electrical purposes, a minimum of 96 per cent. conductivity is stipulated, and so long as this is the case, it would rather appear that, from a manufacturer's point of view, one would not feel inclined to pay a higher price for wire in order to ensure a higher conductivity; this being so, the fact of Elmore copper being stated as of a higher conductivity than the ordinary English wire would not necessarily command for it any advance in price over the present commercial copper.

Now the Elmore process for the manufacture of copper wire is, commercially speaking, untried, and it may be often noticed that what is originally claimed in prospectuses of companies put before the public, do not afterwards, in commercial practice, work out quite so well. On the other hand, at Mons. G. O. Mouchel's factory the manufacture of copper wire has been carried on commercially for some years on a very large scale. Therefore one can hardly admit the great advantages in high conductivity copper wire in which one would be led (or, rather, misled) to believe by the Elmore prospectus.

## THE LANE-FOX PATENTS.

WE hear from several quarters that Mr. Lane-Fox and his associates are contemplating taking action against a number of people with regard to their using their dynamos, accumulators, and incandescent lamps in conjunction with each other. Also, that many of the persons who have been notified have been innocent purchasers of plant which they have installed for their own use, and who question the policy of individually contesting this action, seeing that the terms under which they may now compromise appear comparatively reasonable. We think, however, that the mere fact of licenses having been applied for and granted to the uninstructed public, is no evidence of the justice of the patentee's claims, and it would be far better to test the issue with those who are fully acquainted with the subject, and who would be able to defend themselves on the merits of the case *per se*. We are credibly informed that the licenses which have been granted to the Brush Company, for instance, were so granted in consequence of that company, when they relinquished the Lane-Fox patents, having retained the right of working under them, and they can in no way be construed as a recognition by the Brush Company of the pretensions put forth by Mr. Lane-Fox.

We also hear that Mr. Lane-Fox does not limit his claim to the use of a dynamo accumulator, and lamps running in parallel together with a practically constant potential, but likewise claims the use of a battery if charged separately and then discharged; and if a battery be charged from a dynamo, and then discharged, and the battery is employed for running two or more lamps at the same time, he considers that an infringement of his patents. If this be so, to our mind it is a perfect absurdity,—he might as well apply for a patent for the discharging of batteries for lighting purposes.

But apart from all this, we would call on the lighting public, who are, or may be, threatened, to ask Mr. Lane-Fox on what grounds he can pretend to the rights he claims, for we have evidence that incandescent lamps in the form of platinum wires or strips were operated from batteries as far back as 1859, by Prof. Moses G. Farmer, in Salem, Mass., and believe that the house can be shown to-day (or, at any rate, it was a few years since), with the wires remaining in it where these experiments were made and demonstrated, and pamphlets were published with accounts of this matter before the date of Mr. Lane-Fox's patent. Also, at the Paris Exhibition of 1877, the Planté battery was exhibited by Messrs. Breguet, and there one might have seen the combination of a hand Gramme machine charging a Planté accumulator, and discharging its current through incandescent platinum wires. We think there will be no difficulty in proving, from several sources, that that combination was publicly in operation at that exhibition, as well as M. Gaston Planté's laboratory, and at the show rooms of Messrs. Breguet, in Paris. We would therefore advise the public to hesitate before even paying a small acknowledgment of the patents to the Lane-Fox Association in order to save them-

selves trouble. And we would more strongly advise Mr. Lane-Fox and his friends not to commence their attack on the innocent customer for electrical plant, but to test their position with foemen worthy of their steel either in the courts, or, still better, by discussion among a certain number of men who could, at a much less cost, show that the claim for the discharge of a secondary battery through electrical incandescent lamps in parallel is preposterous and absurd.

PERHAPS no epoch in the history of metallurgy has been so marked as that comprised within the last few years.

That period has witnessed the development of the processes for producing aluminium and the consequent great reduction in the price of that metal. This price, however, requires to be brought down to a still lower level before the manifold uses to which the material can be put become capable of great extension. Simultaneously with the reduction in price of aluminium has followed an increase in the price of platinum, a metal which to the chemist and electrician is invaluable. This increase in price has been such as to augment the value of the metal by three times what it was only a few years ago. How important a factor this is may be recognised by the fact that the cost of the platinum leading-in wire of an incandescent lamp is the largest single item involved in the cost of manufacture. How far workable platinum ores are distributed over the globe appears yet to be very imperfectly known, but a recent discovery at Colac, Australia, appears to show that there is hope that a fairly abundant supply of the metal may yet be forthcoming. It is stated in the *Ballarat Courier* that samples of the ore taken from the Otunz Ranges give a return of 1,120 oz. per ton, and that great excitement reigns in the district. Certain doubts have been cast upon the genuineness of the discovery, but it is to be hoped that there is something more than a grain of truth in the announcement.

Welcome Little  
Stranger.

NOBODY seems to have taken much notice of the announcement made three weeks ago, that Messrs. Swan,

Sonnenschein were to publish for the first time on the 4th October, a new penny weekly paper entitled *Electricity*, the editor of which is to be Dr. Julius Maier. The new paper has not yet appeared, and on enquiry of the publishers it was ascertained that the journal would be born on the 15th November. There is, however, already a possessor of the title, for on Saturday, March 29th last, *Electricity*, a weekly newspaper and technical journal first saw the light of day. The publishers were Messrs. Hampton, Judd & Co., of 14, Duke Street, Adelphi, W.C. The second number appeared on April 5th, but after a fortnight's existence it fell into a decline and died. It had, however, been intended to resuscitate the deceased as a penny monthly paper, but the process of cremation had entirely destroyed its vitality and it has never, as far as we can ascertain, again seen daylight. Nevertheless, the fact of the previous existence of *Electricity* does not appear to have been known by the promoters of the new journal until quite recently, and this is the reason for the delay in its publication. We believe the question of copyright is now agitating the minds of the owners of the old and the publishers of the new *Electricity*.

An Electrical  
Collapse.

A SHORT time ago a monthly contemporary came out with a grand flourish of trumpets announcing that in consequence of the progress taking place in electrical applications, it would in future devote a portion of its valuable space to electrical matters. For a short time volts and amperes were thick in the air, while Mr. R. E. Crompton received polite attentions in the way of portraiture and otherwise. This was, however, too good to last. Whether it be that our contemporary has become frightened over electrical nomenclature, or whether it has exhausted its knowledge of the subject we of course do not know, but the peculiar fact remains that, while in one month's issue there was no electrical matter, a spasmodic attempt at revival in the current number has only resulted in a brief notice of Bristol's mining lamp, which is now a matter of ancient history.

Storage Battery  
Explosions.

THE explosion which took place on board Earl Poulett's steam yacht is by no means an isolated case, and our readers will recollect the explosion on one of the Barking Road cars, which shattered all the windows into fragments. Fortunately no one has ever been injured by such accidents, and we are inclined to think that, as a rule, the force of these explosions is not sufficiently great to do more than split the receptacles, although the noise accompanying the action is loud enough to affect even the strongest nerves. These explosions never occur when the cells are open at the top and used in a well-ventilated place. The batteries were actually on the yacht's deck, where there should be plenty of air to carry off any hydrogen gas developed by over-charging; but the boxes were provided with lids having only a small vent hole, thus preventing a ready escape of gas, which might have been just sufficiently mixed with atmospheric air to produce disastrous effects when Lord Poulett struck a wax match and accidentally ignited some of the escaping vapour, which speedily communicated heat to all the neighbouring cells, and probably exploded the whole series simultaneously. This incident caused much alarm; a daily paper states that "electricians could in no way account for it, as it had hitherto been thought that under no circumstances could gas be generated." Mr. Reckenzaun tells us that he experienced explosions with covered cells, having vent-holes, as early as 1882, also at different periods since then, but that neither he nor any one else had been seriously hurt, and that a sufficient supply of air, cells completely sealed, or quite open at the top, will be an efficient safeguard against mishaps of this description. Overcharging of storage batteries must evolve hydrogen, which, if accumulated in a close atmosphere, will produce one of the most explosive compounds when ignited. We give amongst our "Notes" the description of this little mishap as the *Daily Telegraph* has it, but the reference to Earl Poulett's electricians is utterly absurd. His technical adviser knows perfectly well that under certain conditions such mishaps as the one under notice may occur, and the remarks of our gaseous contemporary are therefore quite uncalled for. It is more than probable that as the incident occurred some two months ago the memory of the narrator of this pretty story is at fault, but nevertheless we may point a moral to adorn the tale: never allow these gases to accumulate, and don't search for free hydrogen with a lighted match.

## THE FALL OF POTENTIAL AT THE CATHODE IN GEISSLER'S TUBES.

It has been observed by E. Warburg that whilst in a Geissler tube filled with slightly moist nitrogen the difference of potential between the cathode and a point in the extreme visible limit of the negative glow remained constant, yet when the nitrogen is quite dry a considerable increase of fall takes place as the current passes [*vide* Gilbert's "Annalen der Physik und Chemie," series [2] Vol. XXI., page 545].

This observation has recently been under investigation again, and Warburg now attributes the phenomena to the presence of minute quantities of oxygen in the nitrogen, and shows in a paper in Gilbert's "Annalen," &c., series [2], Vol. XL., page 1, how these traces of oxygen may be removed. Sodium had previously been used for this purpose, but a difficulty was experienced in obtaining this metal in a state of sufficient purity.

Warburg now liberates his sodium within the closed tube in a nascent state by electrolysis through the glass, a portion of the tube being immersed in half per cent. sodium amalgam connected with the negative pole of a battery and heated to 300° C., the cathode of the tube being connected with the positive pole. When the last trace of oxygen has been removed a deep yellow light appears in the part of the tube where the sodium is liberated.

Nitrogen at 2·3 mm. pressure was freed from oxygen in 20 minutes with a current from three Bunsen cells connected with an induction coil capable of giving a 25 mm. spark in air, and making 390 contacts per minute. The excess of sodium was afterwards distilled into a remote portion of the tube. From his experiments Warburg gets the following mean numbers for the fall of the cathode in volts :—

Platinum cathode in	nitrogen	=	232	volts.
"	"	"	hydrogen	= 300 "
Magnesium	"	"	nitrogen	= 207 "
"	"	"	hydrogen	= 168 "

Variations of a few per cent. still remain, but the author is of opinion that in perfectly pure gases the fall is independent of the current strength and of the pressure, being determined only by the chemical nature of the gas and of the cathode, and by the physical condition of the latter.

## THE ACTION OF THE ELECTRIC ARC ON GASEOUS SUBSTANCES AND ITS EMPLOY- MENT FOR DEMONSTRATIONS.

THE action of electricity upon various simple and compound gases has, as our readers well know, engaged the attention of physicists and chemists for many years. A few weeks ago we gave some account of an investigation into the behaviour of certain gases under the influence of the silent discharge [*vide* this paper, September 19th, 1890]. We have now to call attention to some recent work by a German scientist, namely, Herr B. Lepsius.

Lepsius has been studying the action of the electric arc on certain gaseous substances. During the course of his work he has designed an exceedingly interesting apparatus, which can be successfully employed for demonstrating the volumetric composition of various gases. The law of combination of gaseous elements and compounds by volume, which was enunciated in 1808 by Gay-Lussac, has not yet been subjected to as rigorous an examination as that which the laws of combination by weight have undergone.

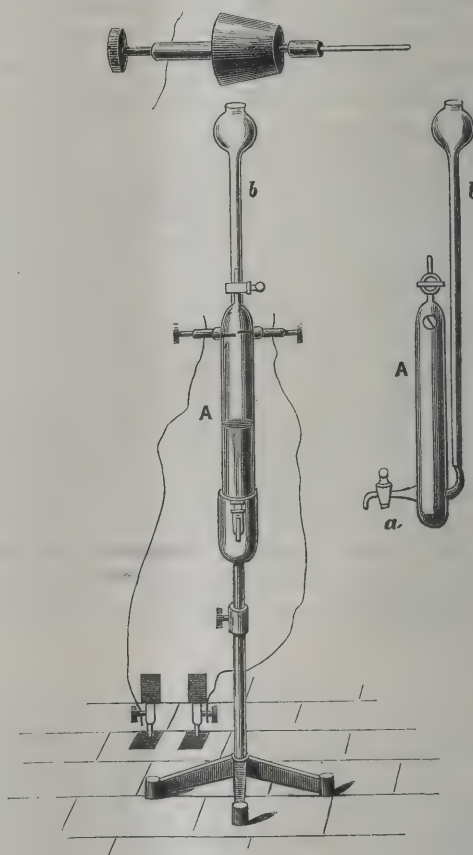

The laws of chemical combination, in so far as they concern the gaseous elements, may be summed up in the following statement: "The gaseous elements combine in the ratios of their combining volumes, or in ratios

which bear a simple relation to these." By combining volume, is here meant the smallest volume of a gaseous element which combines with unit volume of some specified gaseous element taken as a standard. The laws of "combining weights" have been amply verified by accurate experiments; but the laws of "combining volumes" does not stand on so firm an experimental basis.

It is evident, from what is stated in the preceding paragraph, that there is room, if not a demand, for improved methods and apparatus which shall be useful in studying the volumetric composition of gases.

There is already existing a form of apparatus invented by Hofmann, by means of which much good work has been done, but there are certain objections to it; for instance, it can deal only with small quantities of gas, and then the experiment takes a considerable time.

Lepsius's new apparatus depends for its efficiency upon the action of the electric arc. The accompanying sketch gives a very fair view of it. The essential features may be thus described.

A glass tube, A, 40 mm. in diameter and 300 mm. in length, is provided at its upper extremity with a glass stop-cock, and, 40 mm. below the stop-cock, with two lateral tubes, 15 mm. in length and 15 mm. in diameter; it is closed below, but provided with a stop-cock, a, and an upright tube, b, 10 mm. in diameter, as shown in the figure, the whole being placed on a suitable support. The lateral tubes serve for the introduction of the carbon poles, which are about 2 mm. in diameter (or larger if required), and enclosed in metal necks 12 mm. in length, which on the other side fit on the pin (2 mm. in diameter) of a copper rod (6 mm. in diameter), provided with a binding screw.

The metal necks are made of iron or of brass—in the latter case they must be lacquered—and are slit down on one side. The copper rods are fitted tightly into the lateral tubes by means of India-rubber corks, and are of such a length that they overlap each other about 10 mm., the corks being placed eccentrically in the tubes in such a manner that the rods can be brought into contact by slight pressure on one of the binding screws.

A potential difference of 30 to 50 volts is sufficient to give the necessary arc, but it is better to employ, say 60 to 80 volts, and a rheostat; the heat of the arc can then be regulated, so that the glass apparatus and the India-rubber corks are not damaged.

The gas is introduced in the usual way by first filling the apparatus with mercury.

Those who have ever been called upon to lecture before the public or a number of students, and have wished to demonstrate in an intelligible way the volumetric composition of gases, have probably been much inconvenienced by the insufficiency of the commonly known methods for this purpose. Lepsius' new apparatus, which of course is not patented, but may be the common property of all students of science, will, as the advertisements say, "supply a long felt want" in this direction, and, moreover, will prove of the greatest value in demonstrating the truth of certain hypotheses, and in placing the laws of combination by volume upon a sound experimental basis.

The following examples will serve to illustrate the use of the apparatus:—

*Conversion of Carbonic Anhydride into Carbonic Oxide.*—From 80 or 100 cc. of well dried carbonic anhydride is introduced into the apparatus, its volume measured under the atmospheric pressure, is marked on the tube, and the arc is ignited. Decomposition takes place with a brilliant light, and the volume immediately increases; in about a minute decomposition is complete, and after a short time the temperature is sufficiently equalised to allow of the measurement of the carbonic oxide, the volume of which is found to be double that of the carbonic anhydride employed.

*Conversion of Oxygen into Carbonic Oxide.*—About 100 cc. of well dried oxygen is introduced into the apparatus, its volume is noted and the arc ignited; the volume increases continuously, and in one or two minutes the oxygen is completely converted into double its volume of carbonic oxide.

The volume relationship between oxygen, carbonic oxide and carbonic anhydride can be conveniently and quickly demonstrated with a modified form of apparatus, a diagram of which is given in the original paper by Lepsius [*vide* "Berichte der deutschen Chemischen Gesellschaft, Vol. xxiii].

*Conversion of Sulphurous Anhydride into Carbonic Oxide.*—About 80 cc. of dry sulphurous anhydride is introduced into the tube A, shown in the figure; the volume is measured under atmospheric pressure, and the arc is ignited; the carbon burns with a beautiful blue light, the apparatus becoming filled with white fumes; the volume of the gas increases, and reaches a maximum in about 30 or 40 seconds. On measuring the volume of carbon monoxide produced, it is found to be double that of the sulphurous anhydride employed.

That acetylene contains its own volume of hydrogen can also be demonstrated by means of the apparatus shown in the diagram.

This apparatus can be conveniently used for showing means of the electric arc. For this purpose a flask, 15 the formation of water-gas when decomposing steam by to 20 cm. in diameter, is provided with two lateral tubes, through which pass the carbon poles, arranged and adjusted as described above; the mouth of the flask is closed with a cork, through which pass two glass conducting tubes, one reaching almost to the carbon, the other just passing through the cork; the flask is inverted on a stand, and steam is passed in through the longer tube.

As soon as the air is completely expelled, the escaping steam is led under an inverted cylinder full of cold water; if now the arc be ignited, a rapid evolution of gas, consisting of equal volumes of hydrogen and carbonic oxide, is observed.

The same apparatus can be used for showing the formation of water gas from water. The flask, provided with a single delivery tube, is filled with water, placed in an upright position, and a strong current passed; the carbons become white hot, and a mixture of hydrogen and carbonic oxide is rapidly evolved."

## THE ELECTRIC LIGHTING OF MONACO.

[FROM A CORRESPONDENT.]

IN the beautiful but notorious sea-bathing and gambling town, Monte Carlo, a central station for the electric lighting of the town is in course of erection, and is to be shortly brought into play. The concession for this undertaking was granted in February last to the firm of Lombard-Gerin & Co., of Lyons, by the Government of the Duchy of Monaco, for the entire territory of the state. Thereupon the above firm founded a company for carrying out the concession under the style Société Monegasque d'Electricité, having its registered office at Monaco. This company, which was constituted with the co-operation and participation of the Société des Bains de Mer et du Cercle des Etrangers at Monaco, is erecting and otherwise carrying out the above-named electrical works.

The concession for this undertaking was granted on very favourable conditions. For the edification of other projectors, I will recapitulate the more important stipulations.

Article 2 of the concession secures to the company the exclusive right to utilise the public domains of Monaco for laying down leads, underground or aerial, for the distribution of electric currents, whether for lighting or for the transmission of power.

This exclusive right, however, does not interfere with the existing rights of the Société des Bains de Mer, which had previously obtained a concession for laying electric leads for lighting the buildings which are at present its property.

Article 4 fixes the duration of the concession at 50 years, but after the expiry of 25 years the Government may cause the concessionaries to adopt any new means for the more rational distribution of the electric current if they have been found satisfactory in practice.

Article 6 provides for the reversion of the entire conductive network to the town of Monaco after the expiry of the concession. The buildings and the internal plant of the central station remain the property of the company; but the town has the right to purchase them at a price to be judicially determined.

Article 7 gives the concessionaries the right to use the Zipernowsky-Déri-Bláthy system of distributing the current by means of alternating current transformers. The primary tension must not exceed 3,000 volts, and 120 volts is fixed as the limit for the secondary E.M.F.

Article 12 prohibits the use of the earth for the return current. The underground cables must have a single or, if needful, a double lead coating, unless they are laid in wooden boxes or earthen pipes, protected with metal sheathing. The joints for connection and distribution must be fixed in cast iron boxes carefully insulated.

Article 16 binds the projectors to supply current to every subscriber within the line of the streets traversed by the leads. To subscribers beyond such streets, current can be supplied only on condition that they undertake the entire cost of the connection from the nearest point of the conductive network.

Article 17 binds the company in all cases to lay at their own cost the primary conductor for the electric lighting of the ducal palace and the palace of the Governor, and to supply the necessary transformers. The expense of the secondary conductors and the internal fittings in these buildings fall upon the government. In return for the grant of the concession, the projectors are required to supply yearly, without charge, sufficient current for 50,000 10-candle glow-lamp hours of burning, whilst the Government is to pay for any current in excess of this quantity at the figure required from the most favoured consumer.

Article 18. The Government places the ground necessary for the erection of the works at the disposal of the projectors gratuitously for the total duration of the concession.

The work is already in full progress. Two alter-

nating current machines of the Zipernowsky type A<sub>6</sub> (each of 80,000 watts), together with the necessary exciters and transformers, are already set up, and a third machine will shortly be added.

The entire materials for this central station (both the motors and the electrical machines and apparatus) are being supplied by the firm Schneider & Co., of Creusot.

### PASCHEN'S RESEARCHES ON POLARISED MERCURY.

STUDENTS of electricity are familiar with the common laboratory experiment of putting a drop of mercury in some dilute sulphuric acid which contains a trace of chromic acid, and then so fixing the end of a piece of bright iron wire that it dips in the acid, and at the same time just touches the edge of the mercury; under these circumstances, the wire commences a series of regular vibrations which may last for hours.

The usual explanation of these interesting phenomena is as follows: An iron mercury couple is formed when the piece of wire first touches the edges of the globule of mercury; the effect of this is that the surface of the mercury becomes polarised by a thin layer of hydrogen gas, the surface tension of the mercury is consequently increased, the globule becomes more convex, and contact with the iron is for the moment broken. The chromic acid now comes into play, the mercury is depolarised, and the original "flattened-globular" form is restored; the couple is thus formed again, and the same phenomena are repeated and a vibratory movement ensues.

The above experiment, owing to its remarkable character, attracted the attention of the leading electricians of the day when it was first discovered, but its true significance was scarcely appreciated until Lippmann began to work upon it. Lippmann, during the course of his investigation, was led to some experimental results which have demonstrated a marked relation between electrical and capillary phenomena.

One of the most important results accruing from Lippmann's work on those phenomena was the construction of his capillary electrometer. Few readers of this paper probably require to be enlightened upon the subject of Lippmann's capillary electrometer, and detailed description of it may be read in any good textbook. It can estimate very small electromotive forces, and as its electrical capacity is very small, it can show rapid changes of potential. It is not generally recommended for greater electromotive forces than 0.6 of a Daniell.

A short time ago F. Paschen published a paper in "Gilbert's Annalen der Physik und Chemie" (*vide* Series [2], Vol. XXXIX., page 43), in which he discussed the variations which take place in the surface tension of polarised mercury in different electrolytes. In the course of the researches described in this paper Paschen states that he found Lippmann's capillary electrometer, whilst yielding excellent results for electromotive forces of less than 0.9 volt, was quite untrustworthy for values above this limit, on account of the polarisation caused by the liberation of hydrogen gas at the meniscus.

Since Lippmann's electrometer is thus found unreliable, Paschen employed a simple apparatus which, though not so delicate, can be used for large electromotive forces. It consists essentially as follows:—An open U-tube is taken, having one limb about 24 mm. in diameter, whilst the other is somewhat shorter, and only 3 mm. in diameter. The tube is so far filled with mercury that the meniscus reaches the top of the narrow limb. The whole is immersed upright in a beaker containing dilute sulphuric acid and a layer of mercury, so that the meniscus in the shorter limb alone is below the surface of the liquid. Connection is made with the meniscus through the wide limb.

By means of this instrument Paschen investigated

the change of surface-tension of mercury occasioned by polarisation in solutions of sulphuric acid, hydrochloric acid, sodium hydroxide, and various salts. He found that all changes of surface tension take place between the limits of + 0.1 and - 2 Daniell, and in the original paper curves are given which show that up to the maximum it is the anion that exerts the decisive influence, whilst beyond the maximum it is the cathion. The position of the two characteristic points of the curves, the maximum and the point where the electrolysis becomes evident, would appear to depend greatly on the concentration of the electrolytes.

In Lippmann's electrometer, and in Paschen's instrument also, the polarisation seems to be entirely at the meniscus and not at the large anodic surface. When the polarisation attains a constant value the surface-tension also becomes constant.

Temperature influences the results slightly, but not to such an extent as to interfere with the accurate working of the instrument under ordinary conditions.

Since these results were published Paschen has been continuing his researches upon the surface-tension of polarised mercury, specially considering the effect of concentrating the electrolytic solution and seeking to test Pellat's relation between the maximum of surface tension and the point where electrolysis begins.

An account of these experiments may be read in Gilbert's "Annalen der Physik und Chemie," series [2], vol. XL., p. 36.

For sulphuric and hydrochloric acids Paschen found that the maximum increases with increasing concentration, whilst the electromotive force for incipient electrolysis diminishes. It thus happens that for a definite mean concentration the two values become equal, so that it is only for this concentration that Pellat's relation holds good.

The fall beyond the maximum depends on the relative values of the electromotive force for maximum surface tension and for electrolysis. There is little or no fall for strong solution of hydrochloric and sulphuric acid, when the electromotive for electrolysis is far below the maximum.

Other electrolytes investigated by Paschen were solutions of nitric acid, ferrous sulphate, potassium hydroxide, potassium iodide and mercuric cyanide. Nitric acid and ferrous sulphate behave very similarly to hydrochloric acid.

The point for electrolysis is affected by the nature of the solvent. A strong solution of potassium cyanide behaves abnormally, giving a deflection of the meniscus in a direction opposite to that when other electrolytes are employed.

Experiments have also been carried on by Paschen with the so-called Wood's metal used instead of mercury, but the results have been identical in character.

### NEWSPAPER OFFICE ELECTRIC LIGHTING.

THE electric light installation for the new offices of the *Bolton Evening News* has just been completed by Messrs. Ernest Scott & Co., Close Works, Newcastle-on-Tyne, electrical and general engineers.

The installation is said to be one of the most complete, if not the most complete, in Lancashire, and lights the entire premises. The arrangement of lamps is as follows:—

Basement ...	...	46 lamps of 16 candle-power
Ground Floor ...	58	" "
First Floor ...	127	" "
Offices ...	45	" "
Entrance ...	1	" 200 "
Manager's Office ...	1	" 100 "

The whole of the lights throughout the building, with the exception of the offices, are pendants, and each lamp is fitted with a switch, secured to the pendant, so that every lamp in the installation can be switched on or off in the same way as gas.

There are two dynamos to drive the installation of Messrs. Ernest Scott & Co.'s standard "Tyne" type. Each machine is constructed to give an output of from 90 to 100 ampères at an electromotive force of 105 volts, the speed of each machine being 900 revolutions per minute.

As gas engines are used as the motive power for driving this installation, each dynamo has been fitted with a very heavy turned flywheel, supported on an outer bearing, and it has been found that the lights are perfectly steady, which is a result not very often obtained with gas engines unless special precautions are taken.

The current from these dynamos is taken to a main switchboard of a very handsome and massive description. The switchboard consists of an enamelled slate slab, about 5 feet long by 4 feet wide, and is fitted with two of Messrs. Ernest Scott & Co.'s improved coupling switches for connecting the two dynamos in parallel. Four double main switches, with fusible cut-outs on both positive and negative poles, are also mounted on the main switchboard. These switches are used to control the four departments, *i.e.*, basement, ground floor, first floor, and office.

Measuring instruments are also mounted upon the main switchboard, and by simply pressing the key, the pressure and quantity of current can be instantly measured. The enamelled slate base is mounted in a deep oak frame.

The office fittings are extremely handsome, and consist of five polished brass pedestals for the counters, eight polished brass brackets for the desks, one pendant with cut glass globe for the main entrance, containing a 200 C.P. lamp, and a pendant containing one 100-C.P. lamp for the manager's office.

This installation has now been running for some time without a hitch of any kind, and has given every satisfaction.

Messrs. Bradshaw and Gass, of Bolton, are the architects for the new buildings, and have throughout superintended the electric lighting arrangements, and much credit is due to them for the care and attention they have bestowed upon this matter.

INFLUENCE OF ELECTRIC TENSION ON  
THE INSULATION OF CABLES.\*

By A. PALAZ.

THE importance of a good insulation of electric leads grows continually greater, especially since the use of high tension currents becomes more and more general, the rather because the insulation decreases in proportion as the tension of the current increases. This fact was first mentioned by Herr Uppenborn.

The exact determination of the variations of the insulation with the tension of the current presents the greater interest as it enables us to determine if a cable has a tendency to modify the nature of its insulating material in consequence of the prolonged passage of a high-tension current.

*La Lumière Electrique* has recently summed up the measurements of Herr Fordenreuther relative to the determination of the insulation of electric conductors, in the course of which this physicist has incidentally touched upon the question which forms the subject of the present memoir. But this question has quite recently been studied in a thorough manner by Herr C. Heim, of Hanover, who has published his results in the last numbers of the *Electrotechnische Zeitschrift*.

The measurements of Herr Heim have reference to two cables coated with lead and insulated with jute saturated with resin or a mixture of different waxes, as also upon a core insulated with gutta percha. They have been effected by the aid of the ordinary method

which consists in measuring the leakage by means of a very sensitive Thomson's galvanometer.

The Thomson's galvanometer carefully insulated was fitted with four shunts of  $\frac{1}{3}$ th,  $\frac{1}{5}$ th,  $\frac{1}{100}$ th,  $\frac{1}{1000}$ th of that of the bobbins of the galvanometer. The resistance boxes forming the shunts were also insulated with great care. The experimental battery consisted of 330 small Callaud elements to which there could be further joined 60 accumulators, giving a total electromotive force of 460—470 volts. These elements had during all the course of the measurements a very constant electromotive force scarcely varying from 1.06 to 1.02 volts

\* *La Lumière Electrique*.

in the lapse of three months. They were also arranged in groups of 10 so that the difference of potential employed in the measurements could be varied at will.

It is known that temperature exerts a great influence on the insulating power of a dielectric. It was, therefore, necessary to effect the measurements as far as possible at a constant temperature, the more so as they require a long time in consequence of the necessity of completely discharging the cable before each observation.

Herr Heim has taken every precaution to satisfy these conditions, either by plunging the cables into water or by surrounding them with a coating which is a poor conductor of heat.

In order to diminish the residue in the cables, the measurements have been effected in general with a time of charging of only one or two minutes. But the duration of the electrification has a very sensible influence upon the insulation; the insulation after a prolonged electrification is the element which it is important to know in cables with a continuous current. Thus Herr Heim in all his series of observations effected each measurement with an electrification lasting 15 minutes.

It must be noted that in every measurement a beginning has been made with low potentials which have then been gradually increased.

The measurements of Herr Heim have given a conclusive result, which appears clearly from the table No. I.

TABLE II.

That is, that the insulation of the cables diminishes with the potential of the current by which they are traversed.

We do not give the values deduced from each measurement for the insulation of the core of the copper insulated with gutta-percha and of the two leaded cables; we shall limit ourselves to sum up the values in percentages of the decrease of insulation for the different increases of potential.

TABLE III.

Cable.	Ratio of potential in volts.	Decrease of insulation per cent.					
		Duration of electrification in minutes.					
		1	2	3	5	10	15
Gutta-percha	53 : 470	6.0	6.3	6.6	5.4	5.3	5.1
" "	53 : 213	4.0	2.9	3.1	1.7	1.5	0.6
Leaded No. 1	21 : 470	4.8	5.2	9.1	6.8	6.0	6.6
" "	21 : 213	4.6	4.9	7.9	4.8	2.9	3.2
Leaded No. 2	53 : 213	8.5	5.0	5.1	2.0	5.9	7.9

Of the values given in Table I., we see that the decrease of insulation for the greatest variation of potential (50 volts to 460 volts) is about 7 per cent. for the core insulated with gutta-percha, 6.5 per cent. for cable No. 1, and 3 to 4 per cent. for cable No. 2.

The results obtained by Herr Heim on the influence of the duration of electrification upon the insulation of the cables are summed up in Tables II. and III. The latter gives in percentages the decrease of insulation along with the increase of the potential.

These values show that the variations of insulation

with potential are the same for short as for long durations. This conclusion shows that in this kind of measurement it is useless to employ considerable durations of charge.

TABLE IV.

Observer.	Difference of potential in volts.	Duration in minutes.					
		1	2	3	5	10	15
Frœlich	?	1.00	1.11	1.15	1.24	1.33	1.37
Heim	53	1.00	1.13	1.20	1.37	1.35	1.40
"	213	1.00	1.14	1.21	1.30	1.38	1.46
"	470	1.00	1.13	1.19	1.28	1.36	1.42

If we take as a unit the insulation of gutta-percha after a minute of electrification, the values of the insulation after 1, 3, 5, 10, 15 minutes are given in Table IV.; the first line refers to the values given by Herr Frœlich in his treatise on electricity. Lastly, the values corresponding to the two leaded cables studied by Herr Heim are summed up in Table V.

TABLE V.

Leaded cables.	Potential in volts.	Duration in minutes.					
		1	2	3	5	10	15
No. 1	21	1.00	1.25	1.54	1.96	2.83	3.59
"	213	1.00	1.25	1.40	1.96	2.88	3.64
"	470	1.00	1.25	1.47	1.92	2.80	3.52
No. 2	51	1.00	1.37	1.66	2.02	2.74	3.24
"	213	1.00	1.42	1.72	2.16	2.82	3.26

All these results have been obtained at a temperature approximately constant. It remains for us to study the influence of temperature upon insulation, an influence which is considerable, but which is accurately known only for gutta-percha. Its determination will be interesting for leaded cables insulated with a compound of resins and paraffins.

4 41	...	...	0.67	...	
5 12	...	1.02	...	...	

We may also mention the measurements which Herr Heim has made on the insulation of the field magnets of a Schuckert machine in derivation. These measurements have been made both in cold and in heat after having passed a current of 2 ampères per square millimetre into the magnets for six hours. The results in megohms are summarised in Table VI., which shows a decided decrease of insulation with the increase of potential, and, besides, how much the insulation measured in heat differs from that which is measured upon the machine in the cold.

These results prove that the measurement of the insulation of a machine should be made when the latter is hot, and with a difference of potential the same as that at which the machine works.

The values in megohms of the insulation with refer-

ence to the earth of two circuits placed along the sides of a hall are shown in Table VII. The circuit, A, was composed of a copper cable of 19 strands of 1·2 millimetre surrounded first with an incombustible ribbon, then with a ribbon saturated with gutta-percha, and then with cotton steeped in tar. This cable was 150 metres in length; it was fixed upon small shelves by means of ordinary hooks. The circuit, B, was common bell wire of 0·9 mm. insulated with cotton soaked in paraffin. It was fixed to the plastered walls by means of common hooks.

TABLE VII.

Potential in volts.	Insulation in megohms.	
	Circuit A.	Circuit B.
2	0·63	0·124
20	0·58	0·091
2	0·61	0·117
120	0·50	0·085
3	0·75	0·111
20	0·57	0·100
2	0·60	0·119

The results of Table VII. show that in a lighting installation where the difference of potential is 100 volts a battery of few elements may serve to verify the insulation of the cables.

Herr Heim concludes his work by submitting the measurements of Fordenreuther to a very thorough criticism. He shows in particular that Fordenreuther has not taken temperature into consideration, and that certain series of measurements which lasted longer than one day are discussed without taking this factor into account.

PROMISING ELECTRICAL PROGRESS.

THE Shakesperian adage about the tide in the affairs of men which taken at the flood leads on to fortune was, perhaps, never more strikingly illustrated than in the case of some of the electrical enterprises of the present day. Amongst the foremost of these is entitled to be placed the firm referred to in the notice boards conspicuously placed on many buildings in the metropolis, stating that the electric lighting is by Rashleigh Phipps and Dawson. The concern was commenced only three years since in a very modest way in premises in Gray's Inn Road, which had the appearance of having been originally put up as stables, but with alteration, made to do duty as workshops. This happened to be just the time when a large demand was springing up for electric lighting, and by laying themselves out to meet the prevailing tastes, the new firm soon found their productions in such request, that they were compelled to take large works and show rooms in a much better, if more highly rented, locality. At No. 53, Berners Street, they have now what we believe is the most extensive manufactory in this country devoted exclusively to the production of fittings for the electric light, though undoubtedly there are larger establishments in which the making of these goods has become an important branch. In Messrs. Rashleigh Phipps and Dawson's show rooms at Berners Street a very fine display is made of fittings to suit every requirement, every one of which is connected up, so that the effect when lighted can be shown in a moment. The originality of many of the designs may perhaps be partly explained by the fact that they have been thought out from the standpoint of the electrician, and are thus free from the mannerisms sometimes observable in the work of men who have been a lifetime engaged in designing fittings for gas. By means of a staff of artists and designers, special patterns, when required, are produced to harmonise with any particular style of decoration or furniture.

The firm has just issued a catalogue of electric light

fittings, handsomely printed in colours, giving a good idea of the style and appearance of a considerable number of these articles. It is, however, pointed out in the preface that it has not been thought advisable to include in the book some of the best and most elaborate patterns. The publication, indeed, seems intended more as an invitation to those interested to visit the show rooms, where illustrations will be found in sufficient variety of style to meet every taste and requirement. A matter to which considerable attention is given is that of lamp shades, the prevailing material employed for these being silk. A very pretty and striking lamp shade is afforded by mother-o'-pearl shells, the effect of which may be seen in a newly-opened bookseller's shop at the corner of Berwick Street and Oxford Street, where the lamps have been fitted with such shades.

The manufacture of fittings has developed so rapidly, that the present workshops in Berners Street are already found to be too small, and additional room is being made, by excavating below the premises, for sixty additional lathes and an extra engine.

The making of fittings is, however, only a subordinate part of the business of the firm, which embraces the supply of every requisite for the electric light, and the carrying out of all the needful work involved in its installation. As a matter of history, it may be mentioned that six years ago, or more, Mr. Rashleigh Phipps fitted up what was almost the first domestic installation in London using a gas engine and accumulators. This, we understand, has been running almost without a day's cessation up to the present moment. The first year or two we were supplied with figures, which we published at the time, showing the cost of maintenance of this interesting experimental installation. Since that time some of the most important work in the metropolis has been put into the hands of this firm, such, for instance, as the lighting of the Garrick Theatre with about 1,000 lights, said to be the most artistically-lighted theatre in London; the new Tivoli Theatre and Restaurant, which are also beautifully lighted, the fittings for which were designed and manufactured within two weeks from the date of order; and, more recently, the Standard Music Hall, where between 300 and 400 lights have been put in. Amongst large installations of a more private though not less important nature which have been carried out by the firm may be mentioned the new mansion of Mr. Robert Harrison, Shiplake Court (300 lights with duplicate plant); Mr. Warren De la Rue's house, Newmarket (200 lights with steam plant and accumulators); and Messrs. Marshall and Snelgrove's, Oxford Street (complete plant). The firm have compiled and published a list of recent installations, consisting of no less than 74 private houses and 20 houses in which complete plant with accumulators has been installed.

The firm pride themselves on their promptness. The Architectural Association gave a *conversazione* on the evening of the 3rd inst., at the Westminster Town Hall, on which occasion the whole of the rooms were brilliantly lighted, the lamps and shades assuming many different forms and colours, some of them exceedingly artistic. The lighting was carried out by Messrs. Rashleigh Phipps and Dawson, the current being supplied specially by the Westminster Electric Supply Corporation. Owing to this arrangement, even when the rooms were most crowded, the air was tolerably cool. The whole of the work connected with this temporary installation was completed in three days.

Enough has been said to show that whatever others may do, the firm to whom reference is here made are determined to take their tide of prosperity at the flood, and we hope it will lead them safely on to fortune.

A most diversified catalogue of electric light fittings has just been issued by Messrs. B. Verity and Sons. It was, we understand, got up in Paris, and it can be seen at a glance that no expense has been spared in its preparation. It consists of 48 large sheets, each consisting of a number of patterns, including pendants, brackets, electroliers, standards, and every other form in which such articles are made. Nearly every pattern illus-

trated is kept on view in the showrooms of the firm at King Street, Covent Garden, and Regent Street, and the same pattern can be supplied in polished brass, bronze, nickel silvered, or electro silvered. At the show rooms there are also replicas of many of the finest examples of French and Italian girandoles, &c., in mercury gilt, any of which can be fitted for electric light. The price list contains a notice that Messrs. B. Verity and Sons have in preparation a catalogue of electrical sundries, in which particulars will be given of the "Verity patent quick make and quick break" switch, and the "Verity patent safety cut-out," by the use of which it is impossible to fix a large fuse into a block intended for a smaller size. The firm is devoting a large amount of attention to the designing and making of good

## IMPROVEMENTS IN TELEPHONE EXCHANGE SWITCHBOARDS.

THE switchboard in every telephone exchange forms perhaps the most important part of any of the requirements. For all large exchanges of over 400 subscribers the well-known multiple boards are principally used in this as well as in other countries. They have from time to time been subject to much attention and many improvements, while the switchboards for all small exchanges have been comparatively neglected, and many of the oldest and worst type are still at work. We therefore have much pleasure in giving particulars which have been furnished us relating to the switchboard shown by figs. 1 and 2.

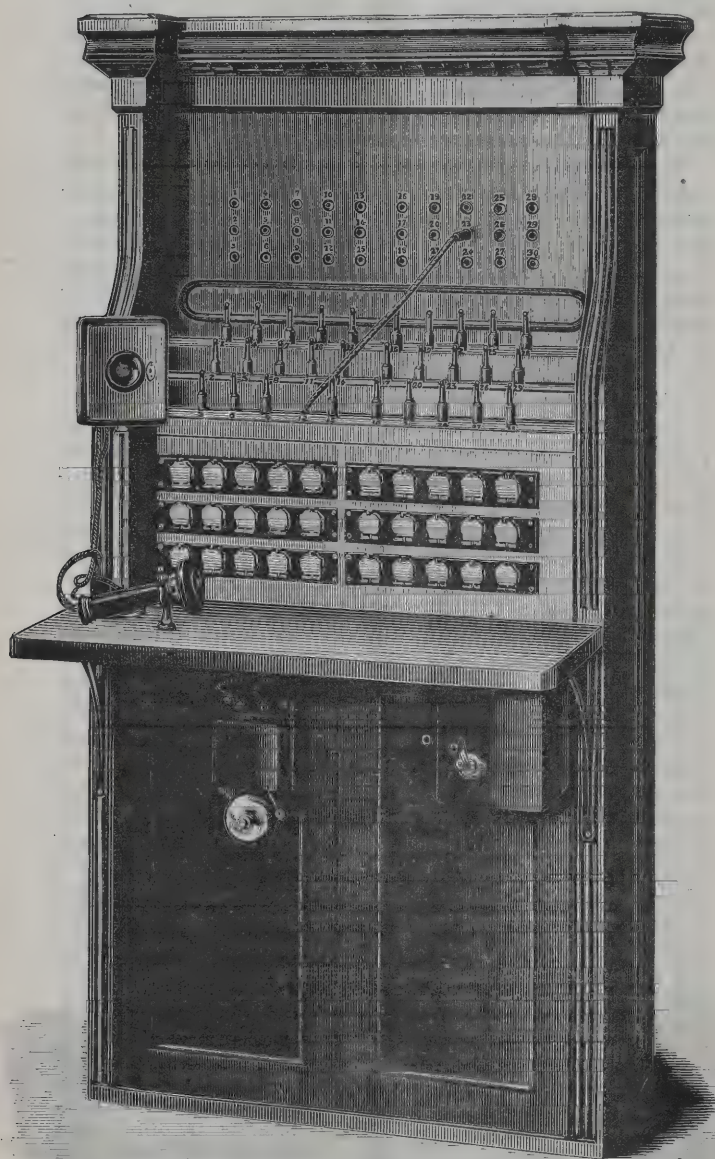

FIG. 1.

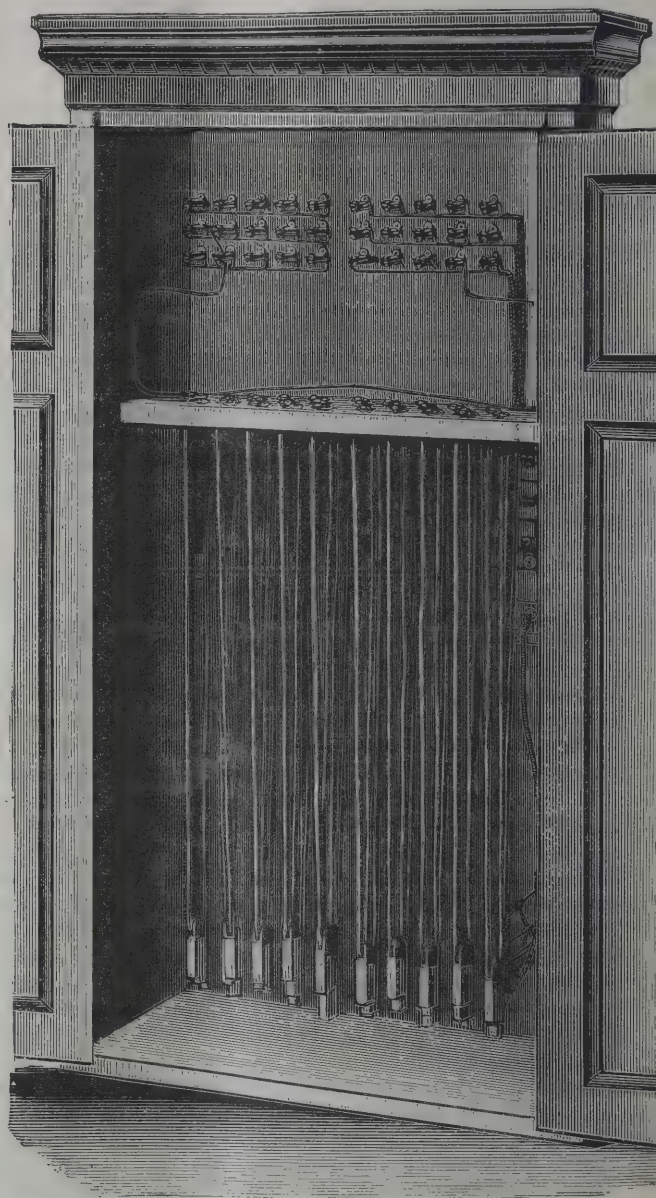

FIG. 2.

switches, switchboards, resistance frames, battery cut-outs, wall attachments, and such like accessories. High-class switch covers in Louis XIV. and other French styles, finished in gold, silver, or bronze, are specially treated, to suit the ornamentation of rooms. We are not surprised to learn that the vast expansion of Messrs. Verity's business through the prominent position they have taken in the electric lighting industry has necessitated their establishing a factory at Birmingham.

**The Electric Light in Brussels.**—In a few days from now the authorities of Brussels will open a competition for a model of the Venetian masts (to which we referred last week) intended to support the electric lighting apparatus in the Grand Place.

These switchboards are known as single-cord boards. They were designed by Mr. D. Sinclair (late engineer for the Glasgow district and now the London manager of the National Telephone Company), and were manufactured by the Telegraph Manufacturing Company, Helsby.

The particular board shown by figs. 1 and 2 (fig. 1 being a front, and fig. 2 a back view showing the cord pulley weights), is fitted for 30 lines, this being a standard pattern for any number of lines from 25 up to 150.

The electrical connections, as shown by fig. 3, are of the very simplest nature, and are so arranged as to give the best electrical and mechanical condition when any two lines are joined together with the least possible

amount of work to the operator.  $L^1, L^2, L^3$ , represent three subscriber's lines led into the exchange.  $J^1, J^2, J^3$ , are the jacks,  $I^1, I^2, I^3$ , the indicators  $C^1, C^2, C^3$ , the wire cords,  $P^1, P^2, P^3$ , the terminal plugs and  $T$  the operator's table. A connecting wire cord with a single plug is permanently attached to each line led into the switch-board in the exchange, and when one subscriber, as, for example, Number 1, is to be connected to another, *e.g.*, Number 2, the operator, inserts the plug,  $P^1$ , constituting the terminal of Number 1 subscriber's line into the jack,  $J^2$ , in the line of subscriber Number 2, thereby also cutting the second subscriber's indicator,  $I^2$ , and earth out of the line to which connection has been made, whilst leaving in circuit the indicator,  $I^1$ , of the line whose terminal plug,  $P^1$ , has been used.

It will be seen that there is the usual line jack and indicator for each line, but instead of the line in the ordinary way going direct to earth after passing through the indicator, it goes, as shown, to a cord, and finds earth at the plug, the latter being placed normally in contact with earth terminals at  $t$  on the table,  $T$ . In this way, there is a cord and plug for each line on the board, and as one end of the cord is permanently

perfectly well for all telephone lines of the ordinary length.

The operating of the board is as follows: say No. 5 wishes any one he rings, his indicator drops, and the operator inserts her general operating plug into the line jack, and receives instructions. If No. 10 is asked for, the operator removes general plug into that No. and rings. When No. 10 replies, the plug of No. 10 line is inserted into jack of No. 5 line, and so the connection is complete. Operator generally waits with her plug tapped on until the two parties are heard in communication. When the conversation is finished, either one or both ring off (it ought to be the party who first applied, but it is difficult to get subscribers to work to any rule), and the operator disconnects the plug, which automatically finds its way back to rest and earth by the ordinary pulley and weight arrangement.

This operation, as compared with the old system, where there were no special keys and cords used, saves about 50 per cent. of the operator's work, and as compared with the system of providing special keys and cords, about 30 per cent. of the operator's work. It is likewise a great advantage on a busy board to have only

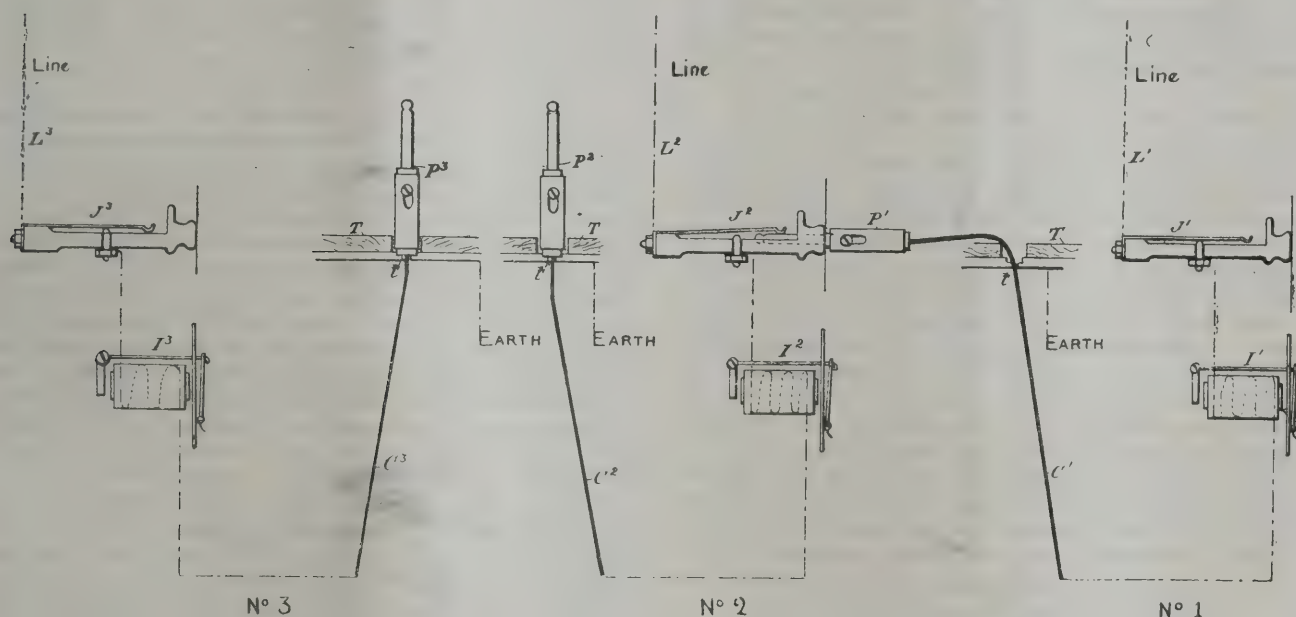

FIG. 3.

attached to the line, it only requires (as has been explained) for the plug of any line to be inserted into the line jack of any other line to make connection between the two, while if a loose cord, with a plug on each end of it is used, as in ordinary small switchboards, it is plain that much more work is necessary in making a connection. Lifting the plug of any line disconnects it from the earth, leaving the indicator in circuit, so that when the plug is inserted into the jack of any other line, this indicator acts as a "ring off" indicator, and the act of inserting it cuts off the indicator cord and plug of the line inserted, so that only *one* indicator is in circuit when any two lines are joined together.

In the old boards both indicators were left in circuit, or they were both cut off, left idle, and a special ring-off indicator provided in the cord circuit; but this was hardly ever carried out in practice on small boards. On the old boards, indicators were wound to a resistance of about 80 ohms, so that with two in circuit the resistance to stable measurement was 160 ohms, which, with the amount of self-induction and retardation, produce very bad effects upon the communication. The indicators adopted in these boards are somewhat of the old type, but joined up in parallel, so that the ordinary resistance is about 20 ohms. These are found to act

one half the number of cords to deal with, as it prevents any confusion to a great extent.

This system was first introduced about three years ago, and it is now extensively used in this country, and continues to grow in favour. Several switchboards of this kind have been supplied for use abroad, and have given much satisfaction.

## SOME NOTES ON OVERHEAD LINES.

By STUART A. RUSSELL.

THE purpose with which these notes have been written is not to discuss the general question of overhead lines, but rather to direct particular attention to that part of the subject which deals with the mechanical strains which they have to withstand; and to compare the present practice as regards overhead electric light and telegraph lines with the regulations for the construction of the former which have been issued by the Board of Trade.

Having recently had occasion to work out the particulars of an overhead line, I was somewhat

astonished to find that the Board of Trade regulations required it to be so much stronger and heavier than has been previously considered necessary; and it appeared to me to be worth while to draw attention to the comparison mentioned above, in the hope that others, who are interested in this matter, would be able, by quoting their experience, to bring together a mass of practical information which would help in the drawing up of a specification which, whilst providing for a perfectly safe line, would not entail needless expense on its construction.

The chief reason of the increased weight of the line is to be found in Section 29 of the regulations\*, which specifies for a wind pressure of 50 lbs. per square foot, and a factor of safety of six for the suspended wire, and of twelve for all other parts of the line; whereas previous practice has assigned a much smaller value to the wind pressure, and has generally used a factor of safety of four. Here I may mention with regard to wind pressure, that there seems to be considerable doubt as to what is the actual effective pressure on a suspended wire; no reliable experiments on the subject have been made and published so far as I can find; and values varying from 0.5 to 0.75 are given by different writers to the coefficient, by which the pressure exerted on a plane surface perpendicular to the direction of the wind has to be multiplied to get the corresponding pressure on a suspended wire. The value I have given to this coefficient is 0.6, thus making

$$\text{the pressure on the wire per foot run } P_1 = \frac{0.6 \times P \times d}{12}$$

= .05 P d, where P is the pressure per square foot on a plane surface, and d is the diameter of the wire in inches. For comparison, the particulars of several lines are given in Tables I. and II.; the former being for lines erected in accordance with Board of Trade regulations, and the latter for lines such as would be erected in accordance with what I believe has been usual practice. In both cases the cables are insulated with vulcanised India-rubber to the thickness specified by the Board of Trade, and then taped and braided; the suspension wires are of stranded steel, and the span and dip are respectively 200 feet and 5 feet.

These tables show how considerable is the increase required by the Board of Trade in the size of the suspension wires, and if we now suppose such lines erected on the housetops, and calculate out the strains on the

supports, we shall find that it will be necessary to provide saddles long enough to take a bearing on two or more roof principals, and that the difficulty of finding good anchorage for the stay wires will be very considerable; indeed, in some cases, it might even be necessary to rebuild a great part of the top of the house before it would be strong enough to bear the strain. It must here be borne in mind that the factor of safety for the supports is 12, and if this is to be applied to the roof of the house as part of the support, I am afraid we shall not be able to find many that will satisfy the specified conditions. Tables I. a and II. a give the strains on the supports and size of stay wires for double conductor lines of 7/20 and 19/15 cables; the former for a wind pressure of 50 lbs. per square foot and a factor of safety of 12; and the latter for a wind pressure of 20 lbs. per square foot, and a factor of safety of 6.

9/15	355	502	7/16	355	227	750	

Coming now to the consideration of overhead telegraph lines, I propose to compare some data concerning the Post Office lines given by Mr. Preece, in two papers read before the British Association, with the regulations of the Board of Trade; and to point out the modifications which would have to be made in Mr. Preece's figures, before the practice of the one Government Department would conform to the demands of the other. The paper read at the 1887 meeting gives a table of spans, dips, and strains, at various temperatures for the three wires most used by the Post Office; and also states that a factor of safety of 4 is allowed for all wires at minimum temperature, and that the calculations have

been made from the formula  $d = \frac{a^2 w}{8t}$  where "w" is the weight of one foot of the wire. In Table III., a part of Mr. Preece's table is reproduced; and, for comparison, the length of span  $a^1$  is given in each case which would correspond to the same dip, if the permissible strain in the wire  $t^1$ , and the resultant pressure

\* See ELECTRICAL REVIEW, 17th October, p. 461.

From this it will be seen that the Board of Trade would require from three to four times as many poles to be used according to the size of wire ; a change which would add considerably to the cost ; and would, by increasing the number of insulators, seriously diminish the insulation resistance of the line. Of course the number of poles need not be increased to such an extent if a greater dip is allowed ; but a limiting maximum dip is soon reached in lines carrying several wires, owing to the increased danger of contacts when the wires are swayed by the wind ; and even a dip of 10 feet would only allow of a span of 180 feet for the iron wire, and of 142 feet for the No. 14 copper wire.

Mr. Preece's other paper, which was read at the 1885 meeting, deals with the strength of wooden poles, and gives some very valuable experimental results obtained at the Gloucester Road factory, concluding with two tables giving the safe diameters of poles for 60-yard spans of 17 and 20 wire lines, calculated for a wind pressure of 18.75 lbs. per square foot with a coefficient of 0.6 and a factor of safety of four. Comparing these figures (which, it may be noted, Mr. Preece says are well confirmed by the results of practice) with those specified by the Board of Trade, it will be seen that the wind pressure in the latter case is  $2\frac{2}{3}$  times that in the former ; and therefore for lines which are otherwise similar, the moment of pressure on the pole will be increased in the same proportion. Since, however, the Board of Trade factor of safety is 12, or three times that used by Mr. Preece, the actual strength of the poles must be as 8 to 1, which means, if they are of circular section, that their diameters must be as 2 to 1. If the length of span is reduced as in Table III., there will be from 3 to 4 times as many poles required, each of which will need to be from  $2\frac{2}{3}$ rd to 2 times as strong as those given by Mr. Preece for his longer spans.

A consideration of the results given above naturally leads to the question, are all the Post Office lines and all the electric lines absolutely unsafe, or are the present regulations of the Board of Trade unnecessarily stringent ? The answering of the first part of this question, so far as it relates to the telegraph lines, may well be left to the engineers of the Post Office, who have the experience of many years to guide them ; and, with regard to the electric light lines, I believe I am correct in saying that, in London at any rate, no accident has happened through mechanical weakness, although some of them were exposed to the storm of December 26th, 1886, which played such havoc with many of the overhead lines throughout the country. From these facts I can only come to the conclusion that the Board of Trade regulations are needlessly stringent, and that if they are enforced they will be the cause of a considerable useless expenditure of money ; so much so, indeed, that the regulations might almost as well forbid the use of overhead lines at all, as their cost will be so nearly equal to that of putting the cables underground. As an advocate of underground work whenever possible, I am generally glad to welcome everything which will increase the use of subterranean cables ; but, at the same time, I cannot but regret any unnecessary increase in the cost of overhead wires, seeing that they may do

such excellent service in opening up new districts, which, from the small number or scattered positions of their lights, are practically shut out from all chance of an electric service by underground cables ; and for this reason I would be glad to see an alteration in the Board of Trade regulations, which, while providing for a perfectly safe line, would yet allow of that line being erected at a moderate cost.

THE SARDINIA STREET STATION.

THE largest station of the Metropolitan Electric Supply Company is situated in Sardinia Street, at the side of Lincoln's Inn Fields, W.C., and is the first to be carried out in so far as the internal arrangements are concerned, by the English Westinghouse Electric Company on its well-known system. The erection of the station was commenced in the early part of 1889, and the building was completed just over a year ago. At the time, however, only half of the generating plant was installed, but now the whole of the machinery is in position and the station may be considered as practically complete. The station occupies a large area of ground, and has recently been increased in size by the acquisition of an adjoining building which was formerly used by a basket maker, and which is now utilised partly as a storeroom and partly for housing a portion of the staff.

There are two entrances in Sardinia Street, one giving access through the offices to the south side of the station, and the other being a cart entrance for coal waggons to pass into a large shed. Underneath this shed is a large vault capable of containing 500 tons of coal, which is shot down through trap-doors. On the eastern side of the shed is situated the fuse room, a large oil room and a store room for engine and dynamo bearings, bolts, and other replaceable parts of the machines. The station itself, which is a two storeyed building, is on the western side of the shed, and the boiler house forms a separate building on the north of the station. This house contains a battery of twelve Babcock and Wilcox boilers, five being erected on one and seven on the other side. They are each of about 210 H.P., are all connected together by a ring of steam piping, and work at a pressure of 150 lbs. There are three Worthington pumps which supply water to three feed-water heaters of the Babcock and Wilcox type. A fan is in course of erection so as to allow of the use of forced draught in order to get up steam quickly, as for instance on a fog suddenly occurring. In the middle, and throughout the length of the boiler house, is laid a narrow gauge tramway for coal trolleys, the rails terminating inside the large vault already mentioned. Thus the coal can easily be conveyed to the boiler furnaces.

The engine room occupies the ground floor of the station, and is very spacious and lofty. A wide central passage has been arranged longitudinally, and on either side are erected five Westinghouse compound engines. Of these 10 machines, five are of 250 H.P. each running at 280 revolutions, whilst the remaining five are of 300 H.P. each and make 250 revolutions a minute. These engines are the largest of the Westinghouse type yet introduced into this country. In addition to these, there are installed in one corner of the engine house three smaller engines of 65 H.P. each, the speed being 300 revolutions. These three engines actuate the exciters. Steam is supplied from a main steam pipe, asbestos jointed, arranged in the form of a ring, suitable branch pipes being conveniently led off. The foundations for all the engines are very well and solidly constructed, being composed of concrete and brickwork. From the large flywheels the belts pass up overhead at an angle of about 30° through belt holes into the dynamo room on the upper floor. The latter is an equally spacious and lofty room containing 10 Westinghouse alternators running at 1,050 revolutions, and having an output of 125 kilowatts each, the pressure being 1,000 volts. The three exciting dynamos, which are also of the Westinghouse type, run at 900

revolutions with an output of 300 amperes at 100 volts, and any one is sufficient to excite the field magnets of six alternators.

The switchboard is a very complete and elaborate arrangement. It is mounted upon panels of polished block slate along one side of the room, with a space of about 30 inches left behind for connections. All the wires to switches, cut-outs, resistance frames, &c., here converge, the instruments for each machine being placed on polished mahogany boards one above the other, with the switches within easy reach, giving ready manipulation and inspection. The switchboard can properly be divided into three distinct parts; first, the exciter switchboard; second, the alternating current dynamo switchboard; and third, the distributing circuit switchboard. Each exciter is operated from the first-mentioned portion of the board, and is entirely controlled by the apparatus there. The latter consists of three rheostats which are in the field circuits of each exciter, the three main exciter switches and the multiple arcing switches for throwing the three exciters together. This is usually done only on changing over from one machine to the other. The second portion, or alternating current dynamo switchboard, consists of two single pole switches for each dynamo, one double pole exciter switch for each dynamo, one ammeter and one field rheostat. By throwing in the main dynamo switch, the operator simply connects the dynamo to two trunk line wires running on the back of the board from end to end. There is a corresponding set of wires for each of the alternating current machines, and it is impossible by any manipulation of the switches on the dynamo switchboard to throw two dynamos in parallel or to short-circuit one dynamo through another, should one be standing still, and the other running at its full E.M.F.

The third portion of the board consists of a dynamo changing switch, a complete set of plugs for cross connecting any dynamo to this particular switch, an ammeter, compensator, and a voltmeter for each of 20 circuits.

There is also in each of the distributing circuits a transformer which is used simply to furnish a secondary current to the circuit voltmeters. The latter reads at 100 volts when the high tension current is at 1,000, the ratio of conversion being ten to one.

Each of these main distributing circuits has also a compensator in the voltmeter circuit. This compensator is set to allow for a certain percentage of drop, whatever it may be, on the line, and by its action on the voltmeter circuit, the reading of the instrument (which is zero reading), is affected in proportion as the load comes on the circuit. Consequently it is only necessary to alter the rheostat in either the main exciter circuit or field circuit of the individual machine, in order to bring the needles back to the zero point, thus allowing for the drop in E.M.F. on the distribution circuit.

From the switchboard proper in the station, the twenty circuits from the corresponding number of distribution circuit switches are led to the fuse house across the yard. The twenty circuits are again subdivided as necessity demands. In some cases one of the twenty main distribution circuits will be divided again into six, or the entire current from one of these main circuits may be taken out by one cable. The object has been to subdivide the lighting circuits as much as possible, but up to the present no necessity for this subdivision has arisen, other than that due to shutting off the current in order to connect a new subscriber. Each of the fuse boards in this house consists of six single pole switches, and six fuses of the Wurts patent. These while quite open, absolutely prevent any chance of an arc being produced between the binding posts, if by any means the external line should become short circuited. Each circuit is labelled with the name of the street in which the cable is laid, and any circuit can be cut out as desired. These cables are then carried into a cellar underground where the street mains are brought in. The fuse room is fitted with an elaborate set of testing apparatus.

The cables employed by the company are of the well known Silvertown type, the largest size used being 37/16, and the smallest, 7/16. The conduits consist of iron pipes, cast vertically, and ranging from 3 inches to 5 inches in diameter. They are partly laid under the footpath, near the kerbstone, and partly under the carriage way. In some cases, owing to the existence of high cellar arches, &c., the conduits have had to be laid so that their upper surfaces are almost in contact with the flagstones. Junction boxes have been provided at suitable intervals, and the house connections are made by means of loops, no T joints being used except in Lincoln's Inn Fields, where mains were first laid.

On each consumer's premises are installed a Shallenberger meter, which type, it will be remembered, has come into extensive use in the United States; a Westinghouse converter, and a main switch. The interior wiring has to be effected by consumers under the regulations of the company, and those laid down by the Board of Trade.

The mains are laid in rings so as to minimise the danger of extinguishing a number of lights in case of a breakdown. All the stations of the Metropolitan Company are connected together by trunk mains, so that one station may take over the load of the other or a portion thereof if necessary.

Customers are usually charged for light by meter at the rate of  $7\frac{1}{2}$  per Board of Trade unit, which is equivalent to  $\frac{1}{4}$ d. per eight candle-power lamp per hour; but a fixed rate per lamp per annum may be arranged. For instance, the charge for an eight C.P. lamp, burning on an average three hours daily, is £1 per annum. The company's other charges which are for annual rent of transformer, main switch and meter, are as follows: transformer, £1 per annum for every 50 eight C.P. lamp, or a less number; main switch, 7s. 6d. per annum, and meter, £1 per annum. The total cost is thus brought up to 8d. per Board of Trade unit. The station buildings were designed by Mr. Robert Walker, A.R.I.B.A., and Mr. Frank Bailey, A.M.I.C.E., is the engineer to the company.

### EFFICIENCY OF THE EDISON-HOPKINSON DYNAMO AND WILLANS CENTRAL VALVE ENGINE.

VARIOUS tests have been published from time to time of the efficiency of Messrs. Willans and Robinson's central valve engine, and the various types of dynamos with which they are combined. At a recent test made at Thames Ditton with a large Edison-Hopkinson dynamo, constructed by Messrs. Mather and Platt, of the Salford Ironworks, Manchester, a result has been obtained giving an efficiency superior to anything previously attained.

The results show an efficiency of engine and dynamo combined, *i.e.*, the ratio of the electrical power available for useful work outside the dynamo to the indicated power of the engine of 86.7 per cent.

The following are the particulars of the engine and dynamo:—Compound double-crank engine with low pressure cylinders, 14 inches diameter, stroke 6 feet, to work with 120 lbs. steam pressure, driving direct an Edison-Hopkinson dynamo, constructed for an output of 110 volts, 475 amperes, at 430 revolutions per minute. The dynamo has a bar armature (patent No. 4,884, 1886, John Platt, John Hopkinson, and Edward Hopkinson), and is shunt wound only, and is fitted with a commutator of hard drawn copper, with mica insulation, with four brushes on each rocking arm.

Resistance of magnets ... 16 ohms.

Resistance of armature ... 0.0055 "

I.H.P. ... 83.3

E.H.P. ... 72.2

Hence efficiency 86.7 per cent.

Consumption of water per I.H.P. hour ... 21.6 lbs.

" " " " E.H.P. hour ... 25 lbs.

In the tests made on this combination, both engine and dynamo were worked to a somewhat higher load than their normal or specified load, and this no doubt would to a slight extent favourably affect the efficiency. Another test was made on a similar combination working at its normal load, with the following results :—

Resistance of armature ... 0.0058 ohms.  
Resistance of magnets ... 15.6 ohms.

I.H.P. ... 85.3

E.H.P. ... 70.0

Hence efficiency ... 83.3 per cent.

The electrical losses in the first instance are :—

Loss in magnet coils ... 756 watts = 1.4 per cent.

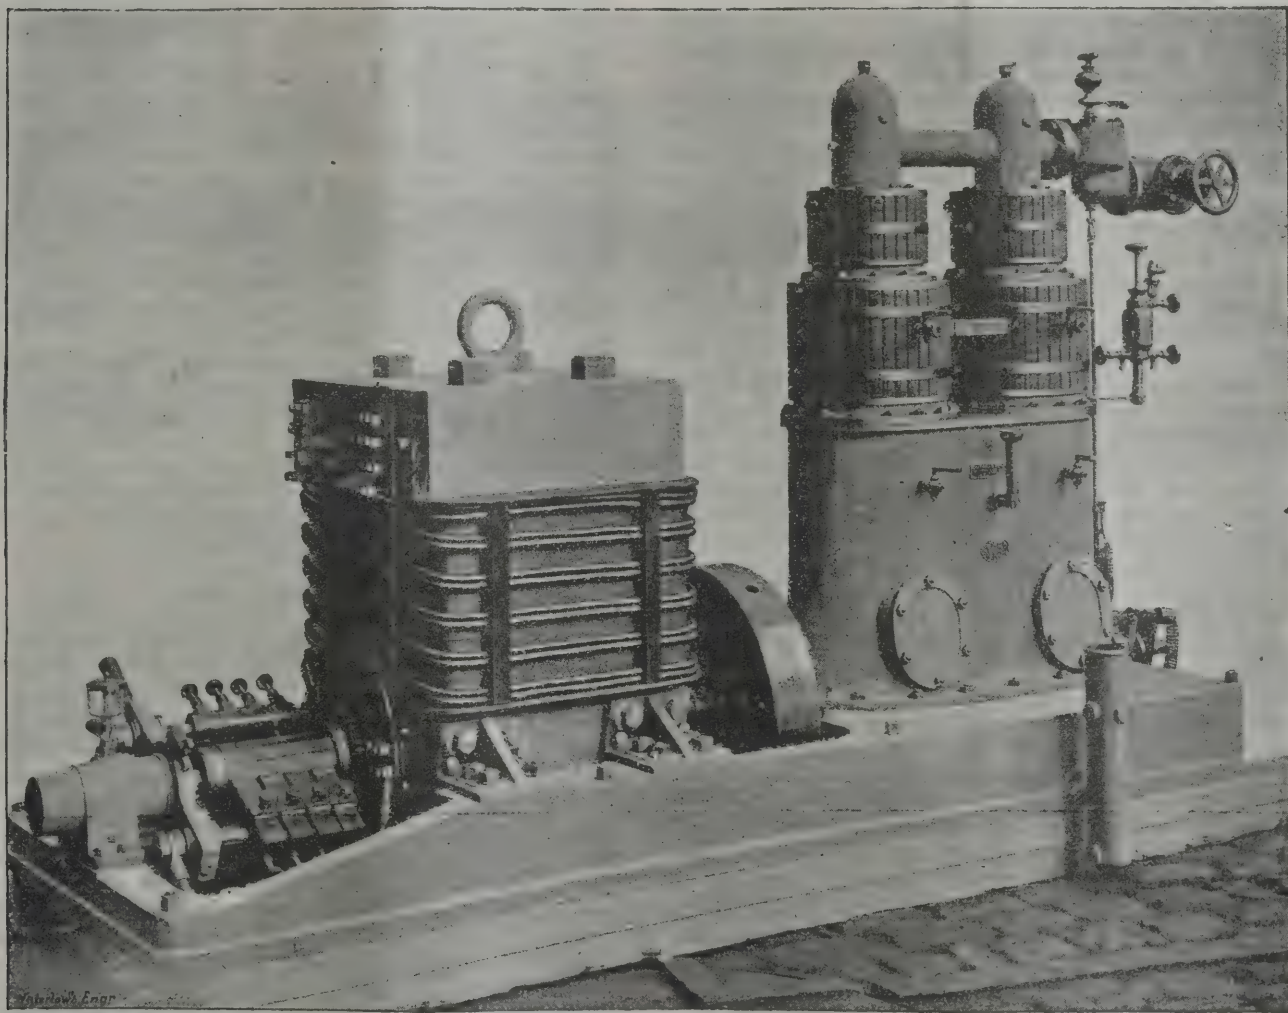

Loss in armature ... 1,386 watts = 2.6 "

Hence electrical efficiency ... 96.0 per cent.

### THE NEW WEST INDIA CABLES.

THE SS. *Westmeath*, chartered for the laying of the new cables which are to connect certain of the West India islands with various points on the continent of South America, left Messrs. Henley's works at North Woolwich on October 15th.

It will be remembered that the *Westmeath* was employed for the laying of the Bermuda-Halifax cable, and on that occasion she was fitted with cable machinery and tanks, which, with some modifications, have been retained as originally designed. The vessel was built at Sunderland in 1882, is classed A-1 at Lloyds, her carrying capacity is 4,400 tons, her length 320 feet, beam 42.4 feet, depth of hold 28 feet, and H.P. 300 nominal. She is said to be a very comfortable boat, extremely steady in a sea way, and possessing unusually good accommodation.

From this it follows that the loss in friction in the engine and dynamo combined is 10 per cent.\* of the indicated horse-power.

Messrs. Mather and Platt have constructed a large number of dynamos for combination with the Willans engine. Those referred to above are part of a number constructed to the order of Mr. Hargreaves for the City installations of Messrs. Spiers and Pond. Others of a considerably larger output are in progress for Messrs. Gatti's central station in the Strand, and for the Westminster Electric Supply Corporation, Limited, installations.

**City Electric Lighting.**—We beg to call the attention of electric lighting contractors to the advertisement in our business columns emanating from the City Commissioners of Sewers with regard to the City lighting.

A large party met on board the ship at Greenhithe, on October 16th. Among those present were—M. Jules Lair, president; M. Paul Wallerstein, general administrator; and M. Ernest Vlasto, director and manager of works of the French Telephone Company. The works company was represented by Mr. Sutton, general manager, and Mr. Hatton, manager of works. Among the actual members of the expedition are Mr. W. S. Seaton, to whom is entrusted the entire direction of the work; Mr. Theophilus Smith, chief of staff; Mr. E. W. Stallibrass, engineer; and Mr. Hall, of Messrs. Henley's, chief electrician.

The total complement on board amounts to 106 persons, viz.:—Staff, officers, and engineers, 22; cable hands and mechanics, 40; crew, stewards, &c., 26; firemen, &c., 13; representatives of the Telephone Company and passengers, 5.

The cable taken out, 1,021 nautical miles weighing 2,558 tons, was manufactured by Messrs. Henley's or the

\* How is this percentage arrived at?—EDS. ELEC. REV.

Société Française des Télégraphes Sous-Marins, who are also the proprietors of the cables laid, by the *Roddam* in 1888, between Cuba, Hayti, Santo Domingo, Curaçao, and Venezuela. A portion of the core was made by the French Telephone Company in their works at Bezons; it was shipped to England, and sheathed at Henley's.

The types of cable and their respective weights per nautical mile are as follows:—Shore end, 8.6 tons; heavy intermediate, 6.05 tons; light intermediate, 3.75 tons; and main cable, 1.72 tons. The core is composed of 130 lbs. of copper (seven strand) and 150 lbs. of gutta-percha per nautical mile.

The sections to be laid on the present expedition are:—

1. Island of Martinique to Paramaribo (Dutch Guiana). Approximate length about 685 N.M.

2. Paramaribo towards Cayenne (French Guiana). This section will not be completed on the present occasion. So much cable as can be devoted to this section will be laid, the end buoyed, and cable completed on the next trip.

3. Mole St. Nicolas, Hayti, to Port-au-Prince, Hayti. Approximate length about 106 N.M.

The sections to be laid on one or more subsequent expeditions are:—

1. Completion of section between Paramaribo (Dutch Guiana) and Cayenne (French Guiana). Approximate length about 252 N.M.

2. Cayenne to Vizeu, Brazil. Approximate length about 575 N.M.

3. Puerto Plata, Island of Santo Domingo, to Island of Martinique. Approximate length about 670 N.M.

The total length of the new cables, including stock, will be somewhere about 2,500 N.M.

It will be remarked that the new cables will place the system owned by the Société Française des Télégraphes Sous-Marins, in direct communication with the Brazilian land lines at Vizeu. The company will thus have at one extremity (Santiago de Cuba) of their system communication with Europe *via* the cables of the Cuba Submarine Company, and at the other terminal (Vizeu) communication with the whole of the Brazilian Telegraph system.

It must be a source of considerable gratification, not only to the French telegraph and telephone companies, but also to the management of Messrs. Henley's, that the disasters, financial and otherwise, at one time freely predicted, have, at all events up to the present, been completely falsified. The French Telephone Company has evidently made considerable preparations for the extending its operations, for the new cable-sheathing works at Calais are not far off completion. It is expected that a good many orders will be received from the French Government. One drawback is, however, present in the manufacture of sheathed cables, in that the core is made at Bezons, and has to be transported to Calais to receive the sheathing. There is certainly but little difficulty in this transport, since a complete system of canals furnishes a cheap and ready method.

### THE BREWERS' EXHIBITION AT THE AGRICULTURAL HALL.

THERE is not, as a rule, much attraction for electrical engineers at this class of show, and the present exhibition is much on a par with those that have preceded it. With the exception of the exhibits of five manufacturers of gas engines, and two small installations of the electric light, we did not observe any apparatus calculated to interest the electrical fraternity. But it is the duty of an electrical engineer to understand what he should avoid bringing his person in contact with, and notwithstanding there are no line wires to speak of at the Islington show, there are many temptations to sample liquid concoctions, which, in the form presented to the taster, are doubtless as deadly as any live wire

conveying a high potential current. Two of the most dangerous of these abominations are to be specially guarded against, the one a brand new Irish whiskey, mechanically given the age of 10 years in about 10 minutes; to the taste bearing more resemblance to the fires proceeding from the abysmal depths than to genuine matured Jameson or Roe. The other bears the outward appellation of claret cup essence, but, in reality, is nearer akin to vitriol than to a pleasant summer beverage; the stuff slightly blistered our finger.

The most prominent show of gas engines is made by the manufacturers of the "Stockport" gas engine. The exhibit is the more noticeable from one of the engines driving a Paterson and Cooper dynamo, which supplies six arc lamps. It is claimed for the "Stockport" engine that it is still as economical as any in the consumption of gas, with an advantage on its side of lower cost of manufacture.

The Atkinson "Cycle" gas engine and the Crossley "Otto" gas engine are also exhibited by the respective manufacturers, but there was apparently nothing in either that could be noticed as improvements of recent date.

Messrs. S. Griffin & Co. have a novelty in a portable hydro-carbon gas engine. On the one frame is placed the usual gas engine and a generator for making gas from petroleum. Economy results from this arrangement, partly from the greater effect produced in the cylinder from ignited gas over the petroleum spray, as in other petroleum engines, and again from the saving of trouble and labour in keeping the machine clean.

The "Campbell" Gas Engine Company also run gas engines of their type, but this is somewhat similar to the "Stockport" in essential points.

Messrs. Harvey Graham show their "Ritter" patent self-acting lubricator for stationary, marine, and locomotive engines. It is worked by a simple mechanical motion from any moving part of the engine; consequently the feed is automatic, and when the engine stops the supply of oil ceases. It is claimed that there is in this machine absolute reliability in working, great saving in oil, and no noise in action.

### REVIEW.

*Rules for the Concentric Wiring of Buildings and Ships.* By J. D. F. ANDREWS, M.I.E.E., A.M.I.C.E.

These rules are the outcome of the author's experience during many years practice as a specialist in the employment of concentric wiring, and he hopes that they will form a guide showing those interested in the introduction of the system the importance of carrying out the work in a uniform and substantial manner, applicable to a large systematic commercial business.

An advertisement on the cover sets forth the advantages of the concentric wiring over the two-wire system, and claims a greatly reduced fire risk, for the reason, as the author elsewhere states, that although electric lighting is undoubtedly safer than any other means of illumination, still many fires have taken place, the causes of which have been a source of study and discovery to many minds, with the result that they have been traced to four causes: first, when the two wires are brought accidentally into contact with each other; second, when a bridge of poor conducting power forms between the two wires; third, when the wires get broken by accident or corrosion, and the electricity jumps across the gap; fourth, when any derangement takes place in the switches, fuses, or fittings whereby a loose contact is made. Of all these sources of danger in electric light apparatus and wiring there is only one—namely, the first, for which a special apparatus has been invented to check its effect. The name given to this contrivance is the fuse or cut-out, and it consists simply of a wire of metal which is easily fusible, and as it is the nature of electricity to generate heat in its conductors, this wire, which forms part of the conductor

to the light, fuses, if the current passing increases to an excess, which is what takes place when the two conductors are accidentally brought into contact.
